It does not suffice to assume that the adult may be dealt with exactly like the child, or that the management of acute stenosis, with its associated state of helplessness and exhaustion on the part of the patient, is identical with that of chronic stenosis. Novelty may yet be discerned in the presentation of the facts, as regards both the technique and the possible scope of the operation. The first glance at a patient of large stature, of unmanageable *avoids*, with a large, thick neck, recumbent on a bed, cyanotic, and perhaps moribund, respiration being reduced to laborious gasps, will serve to flood the operator's mind with important distinctions with reference to intubation.

Such, in fact, was a preliminary case in which I did not perform intubation but substituted tracheotomy. In the absence, at that time, of published precedent, I feared lest my finger as a guide might fail to reach the larynx, or that spasm of the glottis might be provoked, or that the recumbent position, unfamiliar in connection with intubation, might so prolong the time of placing the tube that life's spark would be wholly extinguished. These contingencies deterred me then, and, in the light of subsequent experience, they must still be accorded due consideration, although in a similar case I should now feel justified in making a single attempt at intubation, with all preparations completed for a hasty tracheotomy.

CASE I.—A girl, sixteen years of age, of adult stature, presented the usual symptoms of stenosis from extension of pharyngeal diphtheria to the larynx. She was too ill to move from the bed, the left side of which she occupied, but her head and shoulders were raised by pillows. At first I sat upon the edge of the bed to the patient's left, but was conscious then of an awkward twist in my own posture, and fearing this might imperil success, I knelt upon the bed immediately in front of the patient, which secured a juxtaposition, and, guided by the sense of touch, introduced the first size of the adults' set of tubes. Aided by antitoxine, convalescence rapidly ensued.

A more satisfactory arrangement would have been to move the patient to the right edge of the bed and to stand to her right, in which position one's operating arm rises in front of the patient's mouth without awkward twisting of the operator's body.

The next case presents particularly interesting and instructive features.

CASE II.—A young lady, aged twenty-seven years, on the sixth day of a combination of circumtonsillar abscess and pharyngeal diphtheria, had manifested laryngeal stenosis for twelve hours, intense at times and again less, the patient's strength being well maintained. By means of the laryngoscope, the epiglottis, larynx, and

trachea were distinctly observed to be lined with whitish exudate. A culture disclosed *Loeffler bacilli*.

The patient was wrapped with a sheet to secure the arms, seated in a strong, straight-back chair, and the tube placed without difficulty in the usual manner, guided by the sense of touch. My index finger could reach only to the tip of the epiglottis and not to the arytenoid eminences, the usual guide with children. In an hour the tube was expelled by cough. So easily had it been introduced that I deemed it unnecessary to again move the patient for reintroduction, but attempted it kneeling on the bed in front of her. To my surprise the tube would not enter. The next effort was made more deliberately with the patient seated in a chair as at first, and again failed, although I was positive the tube was properly directed. Then I sprayed the throat thoroughly with cocaine, and with the next effort made use of the laryngoscope. The patient was docile, the light good, and the larynx easily seen. Thus did I observe the end of the tube engaged in the larynx, as it were, but stopped by spasmodic contraction of the ventricular bands and interarytenoid fold. I held the tube firmly in position for a few seconds, when the patient made a slight cough, and with it the larynx opened for inspiration, and the tube slipped through the glottis into place.

Aided by antitoxine, the patient progressed favorably for two days and a half, when respiration became gradually but seriously embarrassed, the symptoms suggesting that extension to the lungs had occurred. However, a critical examination indicated that the lungs were not involved and that the tube itself was unobstructed, but that a mass of mucus and perhaps loosened exudate had accumulated in the trachea below and around the tube. I removed the tube by aid of the laryngoscope and found it perfectly open; some mucus only was thereafter expectorated, and the patient instantly again breathed freely. Dyspnoea did not recur, and recovery ensued in due time.

I feel that in both this and the preceding case the patients owe their lives to the combined effects of intubation and antitoxine, but in the latter case the life which was first jeopardized by diphtheria, then saved by intubation and antitoxine, was a second time placed in jeopardy by the mere presence of the tube, and again saved only by its prompt extraction. The symptoms and physical signs produced by the mere retention of inspissated mucus in the trachea and larger bronchi closely simulated diphtheritic broncho-pneumonia, which has been the final chapter in the history of so many fatal cases. The whole chest surface transmitted rattling bronchial-like sounds and exhibited a deficient respiratory murmur, produced solely by mucous obstruction, not in the tube, but just below it. The larger size and more vigorous action of the chest in the adult facilitated the diagnosis from genuine broncho-pneumonia. How often possibly have children been permitted to die for want of a timely extraction of the tube, the operator mistaking this condition for broncho-pneumonia and deeming it unnecessary to subject a semi-moribund child and its friends to the ordeal of extraction in the face of a seemingly fatal complication!

Another point exemplified is the possibility of invol-

untary spasm of the glottis, preventing the ready insertion of the tube. Together the muscles acted like a powerful sphincter, and the passage could not be safely forced. If this can happen in the adult, as was so distinctly seen in the laryngeal image, why not also in the child?

In fact, when one considers how readily spasm is provoked by other laryngeal manipulations, one is surprised that it is not more frequently encountered with intubation.

Dr. Hopkins \* has mentioned having met with unexpected resistance in the passage of the tube in his case of chronic tuberculous stenosis of the larynx—as he says, “a resistance due largely, no doubt, to muscular spasm.” It is satisfactory to have had the suspicion of this possible obstacle confirmed by actual inspection, as in the case just recorded.

As exemplified in Cases I and II, the adult larynx at first evinces greater intolerance to the presence of the tube, so that it is commonly expelled by cough soon after its introduction. This tendency was pronounced in

CASE III, an athletic young man with pharyngeal and laryngeal diphtheria, repeatedly expelled tube after tube as rapidly as they could be introduced. Finally the manipulations, together with the cocaine used, eased respiration to such an extent that the trials were suspended, because he seemed to be doing well without a tube, and so made a good recovery.

Perhaps a tendency on the part of the operator to select at first tubes of too small size for the adult's larynx has conduced to more frequent expulsion.

CASE IV was also one of laryngeal diphtheria in a man aged about thirty-five years, the particulars of which are kindly furnished, from his practice, by Dr. T. Melville Hardie. He says: “The stenosis was great and the membrane extensively developed. The examination was easily made with the mirror, but Dr. Waxham guided the adult intubation tube into the larynx with his finger without difficulty, the man being seated in an ordinary chair. The patient recovered.”

CASE V was one of acute subglottic stenosis of obscure origin, the particulars of which are kindly furnished from his practice by Dr. C. E. Manierre. John C., aged twenty-two years, had recently recovered from a severe attack of typhoid fever. He was referred by Dr. Storer, suffering from a rapidly increasing dyspnea, unaccompanied by aphonia. A constant hoarse cough rendered laryngoscopic examination impossible. A large-sized tube was inserted and worn one week, when it was expelled by cough, and the patient thereafter breathed perfectly well. While the tube was in place he took food remarkably well with the head in the inverted position. At the time a tracheal gumma was suspected, although there were no other syphilitic data, and there has been no recurrence. It was probably a case of acute inflammatory subglottic oedema or infiltration.

The following case, though resulting in lamentable failure, exemplifies difficulties in the technique of in-

tubation peculiar to adults, and is at least suggestive of a degree of hazard which pertains to this operation in acute cases, where exhaustion is already extreme.

CASE VI.—Mr. — was suffering with urgent dyspnoea. An examination disclosed simple oedema of the glottis with secondary oedema of the lungs. It was urged for tracheotomy, by some of the consultants, that the tube would reach lower than by intubation, to which I replied that the primary obstruction was confined to the larynx, the trachea not being subject to closure by acute oedema, and that the secondary oedema of the lungs might still subside if the larynx was cleared. All concurred in an attempt at intubation.

The conditions were unfavorable; the gasping patient, unable to move from bed or to sit upright, could not endure laryngoscopic examination. On introducing the gag it was found that the mouth could not be opened to exceed three quarters of an inch. It was explained that a chronic spasm of the masseter muscles had for years prevented wide distention of the jaws. This was a most serious obstacle, for the index finger could not pass to reach even the epiglottis as a guide. I was about to abandon the attempt and substitute tracheotomy when another intubator appeared and rather urged the effort. I made it and failed. The patient's exhaustion was measurably increased thereby. My *confrère* made a second attempt, which also failed, and the exhaustion of the patient was further intensified so that he was now *in extremis*. I then performed tracheotomy below the thyroïd isthmus in order to satisfy the possible opinion that swelling might extend low down in the wind-pipe. It was deemed necessary to give a little chloroform.

The operation, though hasty, was practically bloodless; soon the trachea was bared and punctured, but, unfortunately, just then the patient expired; nor was vigorous artificial respiration through the tracheotomy tube of any avail, for life was extinct.

Immediately, post mortem the opportunity was taken to further certify the nature of the impediment to intubation which was encountered, as well as to demonstrate the feasibility of the operation generally in cases of acute oedema of the glottis in adult life. The jaws being now forcibly separated, the epiglottis and borders of the larynx could be felt characteristically oedematous, and I inserted the intubation tube without difficulty, its lower end becoming visible through the tracheotomy slit and its head freely overriding the oedematous tissues. This was with the body still in the tracheotomy position, recumbent, and neck distended, I standing to the subject's right.

The complication of chronic spasm of the masseter muscles which prevented the success of intubation in this case would be but rarely encountered; but the jaw is frequently “set” in conjunction with circumtonsillar abscess, phlegmonous pharyngitis, and Ludwig's angina, conditions in which secondary oedema of the glottis may demand either intubation or tracheotomy. My experience would dictate that when the jaws are thus “set” and laryngeal obstruction demands interference, tracheotomy should be selected without further exhausting the patient by attempts at intubation.

High tracheotomy can be done with cocaine anaesthesia only, at least on many subjects, which would

\* New York Medical Journal, February 27, 1892.

avoid the dangers pertaining to chloroform when the respiration is already embarrassed, and it seems that this would have been the better line of action in the case herewith reported.

Attention has been called by Dr. J. H. Metzgerott, late assistant to Professor Schnitzler, and Dr. Hajek, of Vienna, to the liability of pressure decubitus by intubation, especially in oedema of the larynx. He says: "In a case of acute inflammatory oedema of the larynx this occurrence, directly traceable to the pressure of the tube upon the inflamed membranes, followed." He believes intubation to be therefore contraindicated in such cases. This liability must certainly be taken into consideration, but a single consequence of this nature does not settle the point, for it is likely that undue pressure was caused by an unnecessarily large tube. The smallest tube of the adults' set—that which is designed for adolescents—should be selected for first insertion in case of acute oedema of advanced degree. This would supply enough air, and if it was expelled, the next size could follow.

My own cases would indicate that the technique of intubation in acute stenosis with adults is more varied and at times more difficult than with children, and, since it is an operation the success of which is wholly dependent upon manual dexterity and rapidity of action, advance information as to methods will partake of the highest degree of utility.

The responsibility is inestimable. Time and life alike are fleeting, and a few seconds are to determine brilliant victory or ignominious defeat for both patient and operator. I have formulated the following conclusions as to technique, changes in which, however, may be suggested by additional experience:

1. For one accustomed to the use of the laryngoscope, intubation on adults is easier and more certain under its guidance; therefore for a patient of adequate composure and able to maintain the sitting posture this method should be selected.

2. A patient lacking only composure—one whose inclination is to resist rather than to assist the operator—may be closely wrapped in a blanket to pinion the arms and legs, seated in a straight-back chair, the head inclined slightly backward, the mouth gagged, and the finger used as a guide, as with children.

3. A patient lacking strength to move from the bed and composure or strength for laryngoscopic insertion, should be placed close to the right edge of the bed so that the operator can stand to the patient's right side; the head and shoulders should be well raised by pillows, the neck moderately extended, and the method by the sense of touch otherwise carried out. Kneeling on the bed in front of the patient is unnecessary.

4. A patient who is moribund or nearly so may have the tube inserted while in the recumbent position. The operator should be to the patient's right, who should therefore be placed on the right edge of the bed. This

brings the operator's right hand more immediately in front of the patient without awkward twisting of his arm or body.

Spraying the fauces with a five-per-cent. solution of cocaine facilitates introduction by whatever method, and tends to lessen the liability to premature expulsion.

The extraction of the tube is especially easy under laryngoscopic illumination; otherwise it is done in accordance with the same principles as regards the position of the patient as pertain to its introduction.

The author's posture method of feeding subsequent to intubation, by inclining the patient's head and shoulders downward, in which position fluids may be swallowed without gravitating through the tube into the lungs, can be successfully used with adults, but naturally with more difficulty at first than with children, on account of unmanageable weight and size. It is best done by hanging the head and shoulders over the edge of the bed downward nearly to the floor. Dr. O'Dwyer states that in chronic cases in adults the posture method of feeding is even more successful than with children. Here there is more time to learn the trick perfectly and to overcome timidity, which may at first impair the usefulness of the method in acute cases. Meanwhile, adults more readily than children may be fed upon semisolids, such as custards, stiff cornstarch, and oysters, which will slide over the top of the tube without entering it.

Regarding the scope of intubation for acute stenosis in adults, the four cases of laryngeal diphtheria herewith reported, together with one other of which I have personal knowledge, all of which terminated favorably, justify the conclusion that this operation may with advantage be substituted for tracheotomy in that disease.

Concerning acute oedema of the larynx the indications are not so clear. The operation is technically feasible in uncomplicated cases, even when exhaustion is extreme, and I should consider a single attempt justifiable, provided, in order to guard against pressure decubitus, the smallest size of the adults' set of tubes was first selected.

When complicated by having the jaw "set" or by pharyngeal swellings which might obstruct the top of the tube, either or both of which conditions may be encountered in cases of acute oedema of the larynx, secondary to circumtonsillar abscess, Ludwig's angina, phlegmonous angina, retropharyngeal abscess, etc., intubation is absolutely contraindicated and fruitless; efforts thereat can only serve to intensify the exhaustion and suffering of the patient.

There are other acute conditions or acute exacerbation of chronic states which might be remedied by intubation. In a case of arthritis deformans with an acute exacerbation involving the larynx the dyspnoea was so urgent that I expected to be compelled to intubate at any moment for several days, and I believe now that

much suffering and actual danger to life would have been obviated in that case had I done so.

Dr. W. K. Simpson mentions having resorted to intubation in a similar case of arthritis deformans of the larynx.

Traumatic oedema of the larynx, as by scald, corrosion, or fracture, might in suitable cases be treated in this way.

Laryngismus stridulus, or reflex spasm of the glottis, though rare in adults, might constitute another indication.

Also oedema of the larynx secondary to chronic syphilis or tuberculosis might come within the same category, since the oedema may figure as an acute exacerbation provoking sudden and urgent dyspnoea.

The treatment of *chronic* stenosis of the larynx and trachea by intubation is not included within the scope of this paper.

34 WASHINGTON STREET.

## ALBUMIN TESTING.

By ARTHUR R. ELLIOTT, M. D.,

PROFESSOR OF PREVENTIVE MEDICINE AND URINARY DIAGNOSIS  
AT THE POST-GRADUATE MEDICAL SCHOOL, CHICAGO

For practical clinical purposes it may be assumed that normal urine is free from albumin or any substance belonging to the class "proteid." Under various and widely different pathological conditions these bodies find their way into the urine, giving rise to urinary abnormalities of decided clinical significance, and of much interest to the physician.

Until a comparatively recent date, the proteids occurring in urine were classed together as a single body under the term "albumin." It is now known that there are several different proteids of frequent and often simultaneous occurrence in urine, each possessing a widely different significance. So long as they were classed together under one head and considered as a single substance, the problem of the detection of albumin was a simple one. The better understanding which has resulted from recent investigations and improvements in urinary chemistry has placed the matter upon an entirely different footing, and has surrounded this hitherto simple process with many difficulties. The different proteids met with in the urine are: 1. Serum albumin. 2. Serum globulin. 3. The albuminates. 4. Protosees or albumoseæ. 5. Peptones. 6. Mucin. In addition, there are certain bodies which gain access to the urine and give reactions very similar to those produced by albumins. They must therefore be taken into account in testing. These substances are the oleo-resins, or pine acids, sometimes present after taking cubeba, copaiba, or sandalwood, and the vegetable alkaloids excreted in the urine after the ingestion of such drugs as quinine and strychnine.

Serum albumin is the proteid present in the urine in

organic kidney lesions, and consequently possesses the greatest interest for the clinician. In the majority of analyses it is the body we are in search of. There are many methods devised and advised for its detection, many of them delicate, and all of them sufficiently so for practical purposes, were delicacy the only qualification required. Unfortunately, most of these tests, in addition to precipitating serum albumin, also react to other albuminous bodies present. If we bear in mind the widely different pathological import of the presence of these products, it will be seen that the employment of reagents which are not selective in their action may lead to confusion and inaccuracy. In routine clinical work we can eliminate serum globulin and the albuminates from our consideration in testing for albumin. Globulin is nearly always associated in urine with serum albumin. This association is so close that it has come to be considered as of much the same significance as the latter body. The albuminates occurring in urine are acid albuminate, or syntonin, and alkali albuminate, formed by the action of acids and alkalies upon albumin. They rarely exist preformed in the urine, but arise during the application of some of the tests. This most frequently happens with the heat and acid test, and constitutes a possible source of error with that method. With other albumin tests it is not likely to occur and may be disregarded. Other forms of albumin enumerated in the classification given, together with the reaction-producing substances mentioned, can not be dismissed in this manner, but must be taken into account when testing.

The methods most in use for the detection of albumin are: The heat and acid test, Heller's, Tanret's or the potassio-mercuric-iodide method, picric acid, Spiegler's, Millard's, trichloroacetic acid, and the ferrocyanide of potassium tests. All of these, with the exception of the last-named, react to at least two or three of the co-occurring bodies in addition to serum albumin—some of them, as, for example, the potassio-mercuric-iodide and picric-acid tests, precipitating all albuminous bodies. These fallacies indicate that if any one of the methods is to be relied upon and accurate results expected, its use must be surrounded with precautions to prevent error.

In choosing a test for serum albumin great delicacy should not be considered so essential a quality as reliability. In fact, oversensitiveness has been urged as an objection to more than one of the methods. What is required is a test which is of sufficient delicacy and which possesses a selective action for serum albumin, precipitating that body while exerting no action upon other urinary products.

In mentioning the fallibility of the methods usually employed, the ferrocyanide-of-potassium test was excepted as being free from the errors others are subject to. This is an exceedingly simple method, the reagent consisting of a ten-per-cent. solution of ferrocyanide of potassium (C. P.) in distilled water. It is quite stable and possesses the exceptional and essential quality of precipitating

serum albumin exclusively, giving no reaction with other bodies present in urine. It precipitates all modifications of serum albumin, including the albuminates. It can be relied upon for the detection of that body.

To apply the test, proceed as follows: To 10 c. c. of urine in a test tube add 5 c. c. of ferrocyanide solution and then 1 c. c. of acetic acid. Mix by reversing the tube a few times, and if albumin is present a distinct cloudiness or precipitate appears throughout the mixture. The reaction deepens upon standing, and it is well, if any uncertainty exists, to stand the tube aside for three or four minutes (not longer) and then re-examine. The ferrocyanide reagent should invariably be added to the urine first and the mixture then acidulated. This is a very important rule, for upon it depends largely the accuracy of the method. Mucin is soluble in alkaline, insoluble in acid media. If the acid be added first, that body, if present, will be thrown out of solution, forming a cloudiness which is intensified by the addition of the test reagent. If, on the contrary, the alkaline ferrocyanide of potassium be added first, mucin will be held in solution and not affected by subsequent acidulation. This rule should be carefully observed in employing the method. During four years' constant use I have discovered no objection to this test. Applied in the manner described, it is a reliable means for the detection of serum albumin. If peptone, proteose, or other albuminous body exists, this test will not develop its presence. As it is of considerable diagnostic importance to recognize these proteids, other means must be employed for their detection. For the easy accomplishment of this purpose I would recommend the use of the potassio-mercuric-iodide method, according to a scheme which shall be presently described.

Allen insists upon the advisability of filtering the urine before testing, claiming that it can thus be freed from mucin and any error on that account obviated. He directs that the chemical reaction be first ascertained by means of litmus paper, and if it be not sharply acid, advises the addition of acetic acid, drop by drop, until the proper degree of acidity is reached, as shown by prompt reddening of litmus. The urine is then filtered. I can not say that I have always found this procedure accomplish the result alleged, frequently distinct reactions for mucin persisting after acidulation and filtering. Moreover, if the ferrocyanide test is employed and properly applied, this precaution is unnecessary, since that reagent gives no reaction with mucin. If the urine is turbid from any cause, it is well to filter in order to clarify it, and render observation of the analysis more delicate and exact. In this connection it is well to bear in mind the fact that turbidity due to the presence of bacteria can not be filtered out.

Those who have investigated the relative delicacy of the different tests for albumin all unite in naming Tanret's reagent, or the potassio-mercuric-iodide method, as the most sensitive. This quality renders it pecu-

liarily well adapted for the detection of minute traces of albumin. Because of its property before referred to, of precipitating all modifications of albumin, as well as the pine acids and alkaloids, it can not be depended upon for routine use as an exclusive test. This fault, however, becomes a virtue when employed in the manner in which I recommend it. The test reagent is prepared according to the following formula:

Iodide of potassium.....	3.32 grammes;
Bichloride of mercury.....	1.35 gramme;
Acetic acid.....	20 c. c.;
Distilled water.....	64 c. c.

Dissolve the iodide of potassium and bichloride of mercury separately in water, and mix the solutions. The resulting reagent is a double iodide of potassium and mercury. To this the acetic acid is added and the whole is then filtered. The test is applied by mixture either with or without the use of a few additional drops of acetic acid. The precipitate produced by peptones, proteoses, and alkaloids is dissolved by heat. That due to serum albumin, mucin, and oleo-resins is not dissolved, but is rendered more intense by heating.

I submit the following procedure as an easily applied and accurate means for detecting and distinguishing between the different urinary proteids. To a test tube, half full of urine, add from five to ten drops of acetic acid and about one drachm of potassio-mercuric-iodide reagent. If albumin in any form or in the smallest amount be present, a precipitate will result. If there be no reaction, it is proof that the urine is free from all albuminous bodies, and further search may be abandoned. If a precipitate form, it is heated over a spirit flame. If due to peptone, proteose, or alkaloids, it will disappear or become perceptibly diminished, but will remain unaffected or be intensified if produced by serum albumin, mucin, or oleo-resins. In the event of the precipitate persisting after the application of heat, some fresh urine is submitted to the ferrocyanide-of-potassium test. If a positive reaction follows, it indicates the presence of serum albumin, since, as before pointed out, that body is the only proteid affected by this test. A negative result shows the body present to be either mucin or oleo-resins. These can be readily distinguished by adding alcohol to the original precipitate produced by the potassio-mercuric-iodide reagent, when, if due to oleo-resins, it will clear up, whereas if produced by mucin it remains unaffected. Returning to the second alternative: If heating causes a disappearance of the original precipitate the indication is that either peptones, proteoses, or alkaloids are present. The potassio-mercuric-iodide test is again applied to some fresh urine, and the precipitate is shaken up with ether. If it disappears, the reaction has been produced by the presence of alkaloids. If due to peptones or proteoses, it is not dissolved by ether. These two latter bodies may be differentiated by means of the sulphate-of-ammonium test.

The following is a summary of the reactions described:

To a test tube, half full of the suspected urine, apply the potassio-mercuric-iodide (Tanret's) test.

Negative result.....	Albumin in all its forms absent.
	Serum albumin: Precipitated by ferrocyanide of potassium test.
	Mucin: Unaffected by ferrocyanide of potassium test.
	Precipitate undissolved by alcohol.
	Oleo-resins (pine acids): Unaffected by ferrocyanide of potassium.
	Precipitate dissolved by alcohol.
	Peptone: Precipitate undissolved by ether.
	Positive reaction with sulphate of ammonium test.
	Proteose: Precipitate undissolved by ether.
	Negative reaction with sulphate of ammonium test.
	Alkaloids: Precipitate dissolved by ether.

The methods described will be found to constitute a reliable, quickly applied, and easily available means for the detection and differentiation of the proteids occurring in urine.

AUDITORIUM HOTEL, CHICAGO.

## Therapeutical Notes.

**Unna's Varnishes for the Skin.**—Dr. Unna, of Hamburg (*Lancet*, August 8th), read a paper before the Section in Surgery at the recent meeting of the British Medical Association in which he remarked that in 1891 he had brought forward some varnishes for the skin, which consisted chiefly of tragacanth. Tragacanth did not suspend heavy particles well unless it was present in a large proportion, and then the varnish did not spread well. He had found a perfect basis formed by the addition of gelatin to the tragacanth; the tragacanth probably surrounded the gelatin, as the mixtures could be used with drugs which could not be used with gelatin alone. The gelatin and tragacanth were present to the extent of two and a half per cent. each. He suggested that the new basis should be first employed in cases of acute eczema.

**Sozoiadol in Diphtheria.**—Dr. S. Schwarz (*Wiener klinische Wochenschrift*, 1895, No. 43; *Deutsche Medizinische Zeitung*, August 10, 1896) recommends the following treatment, which he considers both prophylactic and curative: In the case of children under two years old, he insufflates the nasal and pharyngeal cavities with this powder every four hours:

R Finely powdered sodium sozoiadolate. 45 grains;  
Flowers of sulphur..... 90 "  
Saccharin..... 15 "

M.

For children from two to four years old, he prescribes equal parts of sodium sozoiadolate and flowers of sulphur, with the addition of saccharin; for those over four years old, sodium sozoiadolate with a little saccharin, without the sulphur.

**The Serum Treatment of Small-pox.**—In the *Presse médicale* for August 12th Dr. A. Bédère gives a brief account of nineteen cases which came under his observation in the hospitals of Paris and of Marseilles. Among

the adults the total quantity of serum which was injected under the skin varied from a pint to a pint and a half, and twice it even exceeded this quantity. Young children received doses of from an eighth of a pint to half a pint, according to their weight. In adults it was often very difficult to inject more than a fiftieth of their weight; in some emaciated subjects M. Bédère was able to inject a thirty-third of their weight, but he never exceeded this dose. These enormous quantities of serum, which were introduced into the subcutaneous cellular tissue, were rather rapidly absorbed and did not provoke any accidents except the appearance, in certain cases, from six to ten days after the injection, of a morbilliform exanthem which was sometimes accompanied by urticarial elevations; ordinarily it was rather pale, rarely generalized, nearly always apyretic, and always of short duration; there were no general troubles.

The serum of heifers, whether they have been vaccinated or not, says M. Bédère, is generally better tolerated by the human organism than horse serum. With regard to the action of the serum of vaccinated heifers on the evolution of small-pox, M. Bédère expects to collect a large number of observations and increase, if he can, the immunizing power of this serum. For the present he simply wishes to show that its application in the treatment of small-pox patients constitutes a rational and harmless medication.

**Pyocetanin in the Treatment of Diphtheria.**—In a number of collected articles by Dr. C. Höring, of Stuttgart, originally published in Betz's *Memorabilien* (*Deutsche Medizinische Zeitung*, August 10, 1896), the author speaks enthusiastically of the local employment of blue pyocetanin in cases of pharyngeal diphtheria. It should be applied several times a day. He would use the antitoxine serum in severe cases, but not to the exclusion of this local treatment.

**Soothing Liniments.**—In the *Journal des praticiens* for August 15th a writer says that for this class of medicaments the indications are numerous, slight attacks of neuralgia, local pains during the course of general affections, and various forms of arthralgia being the principal ones. He recommends the following formulæ:

1. Wine of opium..... 30 grains;  
Chloroform..... 120 "  
Oil of chamomile..... 300 "
2. Hydromel of opium..... 30 grains;  
Chloroform..... 60 "  
Oil of hyoscyamus..... 450 "

If these prescriptions are disagreeable to the patients on account of the oil, the following liniment, which is attributed to M. Ginget, may be substituted. It is not greasy, it produces a sufficiently intense revulsion, and gives good results many times where other liniments have failed:

- |                         |                         |
|-------------------------|-------------------------|
| Floravanti's balsam,    | } each..... 225 grains; |
| Camphorated alcohol,    |                         |
| Hydromel of opium,      | } each..... 150 "       |
| Tincture of belladonna, |                         |
| Oil of turpentine,      | } each..... 75 "        |
| Chloroform,             |                         |
| Acetic ether,           |                         |

**Suppositories for Acute Localized Prostatitis.**—Gucpín (*Journal des praticiens*, August 15, 1896) generally uses the following formula:

- R Iodoform,  
Extract of hyoscyamus, } of each.. ½ grain;  
Cacao butter..... 45 grains.

NEW YORK, SATURDAY, SEPTEMBER 5, 1896.

## COMMENDABLE TESTIMONY IN A MALPRACTICE TRIAL.

THE *Wiener klinische Rundschau* for August 16th summarizes an account of a malpractice case from a journal that it calls "N. Fr. Pr.," which may or may not mean *Neue freie Presse*. It appears that the physician against whom the action was brought had been called to attend a woman in childbirth, and had undertaken some operation which he considered necessary, but had found himself obliged to leave it unfinished and send the patient into a hospital. There an operation was performed and the woman died on the following day. At the post-mortem examination a laceration of the internal organs was found, also a foul canal, and it was concluded that the injuries had been inflicted with the forceps. In the complaint the physician was charged with having displayed lack of skill in the operation.

Two expressions of opinion, says the account, were of noteworthy weight in the case. On the strength of Professor von Hofmann's necropsy, the judge held it to have been shown that the woman's injuries must have been inflicted before she entered the hospital and that the physician's operative procedure was not in accordance with the rules of the obstetric art. Professor Schauta gave expert testimony as follows: "The first question is that of whether the operation was indicated, and to that I must answer yes. In this case I should have done the same thing myself; it accords perfectly with the rules of obstetrics. This I must maintain here in direct opposition to Professor von Hofmann's opinion. The woman's physician, to be sure, inflicted the injury with his instrument. But now comes the question, Is that pardonable or not? As to that, I must say that apparently the instrument deviated from its position in consequence of some slight movement on the part of the patient. The circumstances of private practice in such a case are peculiarly embarrassing. In hospital practice we anesthetize the patient, and she lies perfectly still. In this instance, however, there was no assistance but that of the midwife. I may remark that all of us, from the first to the least, are often so situated as to have to say with regard to mishaps: Something has happened that might have been avoided. There are

disastrous occurrences that are due to the extraordinary difficulties of obstetrics. The present case was one of misadventure, and surely it is not to be attributed to the physician's negligence or ignorance."

The *Rundschau* commends Professor Schauta's testimony from every point of view, and so do we.

## A GRACEFUL ACQUIESCENCE IN AMERICAN IDEAS.

APROPOS of "the Klebs antiphthisin case," as stated by Dr. F. E. Stewart in an article entitled *The Scientific Nature of Our Patent and Copyright Laws*, published in a recent number of the *Journal of the American Medical Association*, Professor Edwin Klebs, in a letter to the editor of that journal, explains the commercial aspect of his connection with the medicinal preparation known as antiphthisin. He says that when he first came to this country, in the autumn of 1894, to visit Dr. von Ruck's institution in Asheville, he was in every respect an entire stranger. Dr. von Ruck proposed to him to become a consulting physician to the institution and the director of a laboratory for experimental research. He accepted the offer for the reason that the institution seemed to him an admirable field for practically testing and perfecting his theoretical ideas.

Dr. von Ruck was the medical director and president of the Winyah Sanitarium and Hotel Company, with which Professor Klebs entered into a contract to serve as director of the laboratory on an annual salary and to assume a financial interest in the institution, leaving entirely to Dr. von Ruck the medical and business management, "as well as the exploitation of substances prepared in the laboratory." He therefore saw no harm in applying for legal protection for antiphthisin, especially as he assumed that Dr. von Ruck was sufficiently familiar with the sentiments of American physicians as to such matters to be able to caution him against doing anything that could be construed as a violation of ethics.

Professor Klebs did not discover until long after that time the repugnance with which most American physicians view the patenting of a remedy or a surgical device, but when he did discover the fact he divined the reason for it. In Germany nostrums are not patented at all, but scientific preparations are; exactly the reverse is the case here, and he who obtains a patent on a medicine is regarded as having put himself on a plane with nostrum mongers. Professor Klebs did not obtain a patent on antiphthisin, as he could not comply with certain requirements of the patent office. He is now more familiar with the customs of the country, and he regrets that he ever made an attempt to protect anti-

plithisin by patent. He accepts the American Medical Association's rule against proprietary medicines as of binding force, but he agrees with Dr. Stewart that some qualification should be made to distinguish scientific products from nostrums. Since bacteriological products have come into use in therapeutics legal protection of the methods of their preparation, not in the interest of individuals, but as a guarantee of their purity and efficiency and as a protection against their production by untrained hands, has become important. Professor Klebs's explanation seems to us perfectly satisfactory, and the change that he suggests in our patent laws appears desirable.

## MINOR PARAGRAPHS.

### THE OVARY AS A DRUG.

A WRITER in the *Gazette médicale de Paris* for August 15th says that the success obtained by thyroid medication induced M. M. R. Mond (*Deutsche medizinische Wochenschrift*, April 7th) to try the administration of ovarian substance in troubles due to functional inadequacy or extirpation of the ovaries. He employed tablets prepared by Merck from the cow's ovaries; they contained equal parts of salt and of ovarian substance. There are three kinds of tablets: 1. Those made from the ovarian substance. 2. Those made from the cortical substance. 3. Those made from a substance which is precipitated at the expense of the contents of the follicles. Up to the present time the experiments have been made with the first and the third only. Cases of total or partial extirpation of the annexa, cases of amenorrhœa with atrophy of the genital organs, and a case of rudimentary uterus with defective development of the ovaries were treated with "ovarine." The amount given was from four to six tablets a day, each containing eight grains. In eight out of eleven cases amelioration or disappearance of the pains was obtained. It is not possible, says the writer, to pronounce a definitive judgment on this mode of treatment, but we may hope to draw some profit from it.

### A HEALTH BOARD INSPECTOR'S CURIOUS MISTAKE.

ON a Fifth-Avenue corner within a stone's throw of Union Square there is an unoccupied house fronting on the avenue, but having an area-way on the side street. This strip of ground is covered with high grass and shows such manifest signs of neglect that the beggars that happen to pass by cast into it the bread, meat, etc., that the kind people of the neighborhood have given them. This refuse food rots and is regarded as offensive. On this account a gentleman who has apartments directly opposite recently complained to the board of health. An inspector appeared in due time at the gentleman's own residence and carefully examined the back yard. He said he could find nothing wrong, but would notify the landlord, inasmuch as a complaint had been made. When the janitor suggested to him that the premises complained of must be those on the opposite corner, he answered: "Oh, no, see that," pointing to the printed heading of the gentleman's letter of complaint.

## ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 1, 1896:

DISEASES.	Week ending Aug. 25.		Week ending Sept. 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	25	6	21	6
Scarlet fever.....	18	2	26	2
Cerebro-spinal meningitis....	1	1	1	0
Measles.....	55	5	26	1
Diphtheria.....	89	15	142	25
Tuberculosis.....	190	93	192	107

**Bishop Lawrence on Vivisection.**—We copy the following from the *Journal of the American Medical Association* for August 29th:

Bishop Lawrence, at the last annual meeting of the Massachusetts Medical Society, June, 1896, gave a pointed rebuke to the antivivisectionists of his State, which was wise and timely. The remarks given below contain the Bishop's reference to that subject and also a recognition of the debt the Commonwealth owes to the altruistic ranks of medicine:

"Speaking not only for myself, but also for the great religious sentiment of this Commonwealth, I can say that wherever one finds any representative member of this society, one is impressed, he is humbled, by the devotion of the doctors to their work, by their instinctive love of their profession, by their interest in the scientific lines of their work, and by the service they devote unweariedly to their fellow men. The public spirit of the physicians throughout this State, in relation to their hospitals, to sanitary movements, and to all other civic movements which bear upon their profession, is recognized; but I can not quite believe that they are sufficiently recognized by the people. They are doing untold work in all those lines. The readiness with which the physicians of Massachusetts and of this society respond to calls, without asking questions as to whether they are to receive money in return or not—and they are sometimes imposed upon—is remarkable. The work is done cheerfully and willingly, and is the best form of charity. I can not, therefore, understand how it can be that a great body of people in this Commonwealth can so far distrust the great body of these physicians—can so far distrust their tenderness, their humanity, their sensitiveness to pain—as to bring any unwise, unreasonable restrictions to bear upon scientific study as expressed in vivisection. The people of this Commonwealth have tender hearts, and though they may be New Englanders externally, they are desirous of seeing that no hurt shall come to the animals. At the same time, it seems to me that into no hands can the welfare of lower forms of creation and the question of vivisection be more confidently placed than into the hands of the recognized medical fraternity of this Commonwealth. In reviewing in my mind the character of the good physician and his value to the community in which he lives, I can not help thinking of another medical man whom, like your president-elect, I have known as a friend and neighbor for many years, and to whose sympathy and help in time of need so many in Cambridge can testify: I mean Dr. Morrill Wyman. He comes of a family in which are united the love of pure science and the love of humanity. I need not remind you of the scientific work of his brother, Jeffries Wyman. Dr. Morrill Wyman unites the qualities of an enthusiastic, earnest, progressive student of the medical sciences, and a most skillful and devoted practitioner of his art. I remember his telling me of the remark of an old lady, a patient of his, upon whom he had just performed a very delicate operation, which illustrates the regard which is felt for such men by their patients. After the operation was over she said to him, rather to his chagrin, 'After all, physicians are but instruments in the hands of God.' But she soon set him at ease by adding, 'But there is a great deal of choice in

the instrument.' If each physician learns, as I hope he does, to regard himself as an instrument in the hands of God, to be more fully developed for his honor and the welfare of humanity, he has within him untold possibilities of usefulness."

**The American Association of Obstetricians and Gynecologists.**—The ninth annual meeting will be held at the Hotel Jefferson, Richmond, Virginia, on Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1896. Railway rates from all points to and from Richmond to this meeting will be one full fare going and one third fare returning on the certificate plan—that is, members on purchasing their tickets to Richmond must secure from the agent of whom they buy the ticket a certificate that they have paid a full fare to Richmond. Blank certificates for such use are kept by the agents. On reaching Richmond they must get the agent's certificate signed by the secretary of the association (Dr. W. W. Potter) attesting that the holder of the certificate attended the meeting. On presentation of this certificate signed by the agent from whom the ticket to Richmond was bought, and signed by the secretary as above stated, the agents at Richmond will sell a return ticket for one third of the usual fare.

**The New York State Commission in Lunacy.**—It is announced that the president, Dr. Carlos F. MacDonald, has resigned from the commission, and that Dr. Peter M. Wise has been appointed to succeed him, the change to take effect on October 1st.

**The Brooklyn Water Supply.**—It is stated that the water supplied to Brooklyn is in unusually bad condition, and that Professor Albert R. Leeds, the chemist, has been appointed to make an investigation and report upon means of remedying the trouble.

**A Proposed Masonic Hospital in Brooklyn.**—It is announced the project of establishing a Masonic hospital in Brooklyn is under consideration in twenty lodges of that city.

**Prince Bismarck a Doctor of Medicine.**—According to the *Union médicale*, the University of Jena has conferred the honorary degree of M. D. on Bismarck.

**Change of Address.**—Dr. Floyd Stewart, from New Orleans to No. 4114 Morgan Street, St. Louis.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending August 29, 1896:*

KINDLEBERGER, DAVID, Medical Director. Placed on the retired list September 2d.

LA MOTTE, H., Assistant Surgeon. Ordered to the naval hospital at Norfolk.

BIDDLE, C., Surgeon. Detached from the Monongahela and placed on waiting orders.

WISE, J. C., Medical Inspector, BYRNES, J. C., and BIDDLE, C., Surgeons. Ordered as a board to convene at Annapolis, September 3d, to examine candidates for admission to the Naval Academy.

#### Society Meetings for the Coming Week:

**MONDAY, September 7th:** New York Academy of Sciences (Section in Biology); Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society; Cleveland Medical Library Association.

**TUESDAY, September 8th:** Medical Society of Virginia (first day—Hot Springs); New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Buffalo Academy of Medicine (Section in Medicine); Medical Societies of the Counties of Rensselaer and Ulster (quarterly), N. Y.; Newark (private) and Trenton, N. J., Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospi-

tal and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery.

**WEDNESDAY, September 9th:** Medical Society of Virginia (second day); New York Pathological Society; American Microscopical Society of the City of New York; Medical Societies of the Counties of Albany and Montgomery (quarterly), N. Y.; Philadelphia County Medical Society; Worcester, Massachusetts, District Medical Society.

**THURSDAY, September 10th:** Medical Society of Virginia (third day); Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Massachusetts, Medical Club (private); Pathological Society of Philadelphia.

**FRIDAY, September 11th:** Yorkville Medical Association, New York (private); German Medical Society of Brooklyn; Medical Society of the Town of Saugerties, N. Y.; Cleveland Medical Society; St. Louis Academy of Medical and Surgical Sciences.

## Births, Marriages, and Deaths.

### Died.

DARBY.—In Brooklyn, on Sunday, August 30th, Dr. Charles S. Darby, aged twenty-nine years.

GOODELL.—In New York, on Sunday, August 30th, Euphemia J. Goodell, wife of Dr. Alfred Goodell.

MACKEY.—In Baltimore, on Thursday, August 27th, Dr. Argyle Mackey, of Washington, D. C.

## Letters to the Editor.

### PRIMARY ERYSIPELAS OF THE PHARYNX.

MILLBROOK, ILLINOIS, August 20, 1896.

To the Editor of the *New York Medical Journal*:

SIR: In your issue of August 15th Dr. William Porter writes under this head of some interesting cases of erysipelas. I should like to add a case which occurred recently in my practice. While I can not say positively that the case is one of primary erysipelas of the pharynx, the course taken by the disease led me to believe such to be the fact.

Miss L. M., aged thirty, a school teacher, a few days after returning from Chicago, where she had been employed, had a severe chill followed by rise of temperature and rapid pulse. She complained only of the usual symptoms accompanying pyrexia, but an examination of the throat showed the pharynx and tonsils to be acutely inflamed, but not sufficiently so to account for the constitutional symptoms, which were quite severe. Under the usual remedies used in pharyngitis, the inflammation began to subside in a day or two, but the patient now complained of pain in the left ear. This was shortly followed by a discharge from that organ, and at the same time, or it may have been a few hours previously, there appeared a faint redness in and around the external auditory meatus. This redness gradually deepened and spread over the entire face and part of the scalp. The temperature rose to 105.5° F., where it remained for two days. I now had on my hands a very severe case of facial erysipelas. The patient recovered.

I might say that upon the first examination of the throat I found the right tonsil partly covered by a small patch of exudation from its crypts. This fact increases the doubt as to whether the case was one of follicular amygdalitis with pharyngitis, the inflammation extending along the Eustachian tube to the middle ear, and the erysipelas starting from the wound made by the perforation of the tympanum, or whether the primary inflammation was erysipelatosus. In favor of the latter diagnosis were the very severe constitutional symptoms in the beginning of the sickness and the fact that, so far as known, the patient had not been exposed to the virus of erysipelas after she left Chicago.

R. BOYD MILLER, M. D.

#### THE CORRUPTION OF LANGUAGE.

NEW YORK, September 2, 1896.

To the Editor of the New York Medical Journal:

SIR: In the *Clinical Recorder*, edited by Dr. W. S. Gottheil, vol. i, No. 3, there is an editorial entitled Some Good Suggestions, which reads as follows:

"Dr. Gould, in an address recently delivered before the American Medical Editors' Association, calls attention to what he terms the unreasoning conservatism that prevails in the spelling of medical words, and attributes it to a dislike of change and ignorance of philology. Dr. Gould is an authority on this subject, and he makes the following recommendations:

"1. Abolish the bothersome *æ*, *œ*, supplanting it by *e*.

"2. Omit *al* to adjectives having already the adjectival suffix *ic*.

"3. Drop the hyphen in words derived from the classic languages, retaining them only in words of English origin when both are nouns. Write *cul-de-sac*, *culdesac*; *anti-toxin*, *antitoxin*; but write *skin-diseases*, *heart-murmur*.

"4. Drop the useless *te* from *curet*, *brunet*, *cigaret*, as we have already done in *quartet*, *corset*, *bouquet*, and cut off the *me* in *program*, *gram*, *centigram*, as we do in *telegram*, *diagram*.

"5. Use figures instead of writing out numbers above ten.

"6. Anglicize foreign terms as far as possible.

"7. Adopt the recommendations of the American Association for the Advancement of Science, and drop the *e* in bromide, iodide, and similar words.

"8. Avoid accents and dieresis.

"We agree thoroughly with Dr. Gould on all these points, and believe with him that the omission of useless letters and terminations will be an economy of time, space, and money, three important items for the over-worked and overread medical practitioner."

After reading these remarks attributed to Dr. Gould, I am extremely sorry that anybody who is considered an authority ever made them.

Any one who has studied for himself the slang of the rabble, or has read Zola literature, is aware of what special delight the lower classes take in applying the word *cul*—for the translation of it I have to refer to a French-English dictionary, since it is impossible to print it in this journal. Some French paper, in order to avoid this word, read: "McMahon (at the battle of Sedan) was wounded in that part of the body without which even a *maréchal* of France can not sit down." Every small boy in Germany knows it, however; the French warriors dur-

ing the time of Napoleon must have used the word very frequently, since they succeeded in popularizing it in Germany. It is certainly amusing to hear that it is derived from a classical language!

*Curet* means one thing—namely, a leather used by sword makers, and *curette* means another. There was never a word *quartette* except the English corruption of the Italian *quartetto*. The French word is *corset*, not *corsette*; the latter is also an English corruption. *Bouquet* in French means a bunch of flowers, and *bouquette* means buckwheat.

A. ROSE, M. D.

#### Proceedings of Societies.

##### AMERICAN LARYNGOLOGICAL ASSOCIATION.

Eighteenth Annual Congress, held in Pittsburgh, Pa., Thursday, Friday, and Saturday, May 14, 15, and 16, 1896.

The President, DR. WILLIAM H. DALY, of Pittsburgh, in the Chair.

(Continued from page 306.)

**Recent Advances in the Surgical Treatment of Malignant Disease of the Larynx.**—Dr. D. BRYSON DELAVAN, of New York, read a paper on this subject. (See page 318.)

Dr. W. P. PORCHER, of Charleston, S. C., said: Some months ago I did an operation for disease of the larynx when I really was incompetent to do it. I decided to do a laryngectomy, but previously did a tracheotomy, putting in a Trendelenburg cannula. I can not imagine anything more suitable to cause the death of your patient than this cannula, as the spring within it seems to become clogged. I barely kept my patient from dying, fortunately discovering that the opening was closed and promptly extracting it. I replaced it with a rubber tube attached to a safety pin. I first tried a hard-rubber tube, but found that it was too short to reach well into the trachea, and it frequently slipped out. The soft-rubber one was made long enough to stay in position. As to doing tracheotomy and laryngectomy at the same time, I would never do it again. It is impossible in cases of chloroform narcosis to tell whether the trouble is due to blood in the larynx or to the chloroform. In my case the patient became cyanotic, and I had to discontinue until he breathed better. The patient stood the operation, as a whole, very well, and the final result was very gratifying.

Dr. CARL SEILER, of Philadelphia, said: I am sorry that Dr. Delavan does not give enough credit to American surgeons in his paper for laryngotomy and tracheotomy. In 1885, after the Detroit meeting, I met Dr. Park, of Buffalo, who did, at a hospital in Buffalo, an excision of the larynx in a man seventy-six years of age. The man was a physician who had been through the Mexican and civil wars. A preliminary tracheotomy was performed and the case was one of epithelioma of the vocal cords. Dr. Park and I operated for an hour under chloroform and did not kill the man. Dr. Park thought he had performed a tracheotomy, but he had not. There was an extra thyroid lobe and he had got between the lobe and the trachea. We simply severed the connection, and introduced a Trendelenburg cannula. I must take issue with Dr. Porcher, as there is no such

thing as a spring in the Trendelenburg cannula. It really is a most admirable instrument in preventing the ingress of septic matter into the lungs. We should be put on record in this country in this matter.

Dr. H. L. SWAIN, of New Haven, Conn., said: While the reader of the paper laid great stress upon the matter of taking out the lymphatic glands in the neck I do not think he said too much, and I should like to add my mite in emphasizing that point, as it will help the future success of the operator in laryngectomy a great deal. I had a case in New Haven a year ago, which was a good example. We had been aware of the enlargement of the glands and a preliminary tracheotomy was done with much profit. About ten days after this we did the laryngectomy, and, as the glands had become entirely normal in size, we did not cut down into the tissues around the larynx to get at them. The recurrence was from the glands, and we think that had they been removed the patient would have been alive. The preliminary tracheotomy was of good effect in this patient in that the trachea and bronchial tubes had been prepared for their new way of breathing before the operation of laryngectomy took place. The patient was much more comfortable, coughed less, and had less of the exasperating raising than patients do in whom previous tracheotomies have not been performed. It would doubtless be a great help to many patients. As regards the Trendelenburg cannula, the modified one is safe, and I do not think the majority of patients need suffer at all from it.

Dr. JONATHAN WRIGHT, of Brooklyn, said: It seems to me that the operation of laryngectomy is one for the general surgeon, one thoroughly skilled in all the technique and possessed of all the resources of his art. It is a serious capital operation, and, in my opinion, it is not fair to the patient that one whose time is taken up with the difficult and absorbing technique of endolaryngoscopic and rhinoscopic operations should venture upon it.

Dr. THOMAS HUBBARD, of Toledo, said: Oedema of the trachea is usually secondary to oedema of the larynx, as has been said, but I have seen two cases in which the larynx showed no oedematous swelling whatever. There was a dangerous degree of stenosis in both. Intubation failed in one. Tracheotomy was performed too late. The other case was one of iodism. There was oedema of the trachea and of the fauces but not of the larynx. I could see two pale oedematous lateral swellings in the trachea. Pilocarpine was administered hypodermically, and as soon as copious diaphoresis was established the tracheal oedema subsided.

Dr. M. J. ASCH said: I am glad to hear Dr. Swain give his reasons for preliminary tracheotomy. So far as the operation of laryngectomy is concerned there is no necessity for it, as it can be done at the same time. As to the Trendelenburg cannula, I think those operating will find that after putting in a tracheotomy tube the trachea can be closed with gauze, and blood prevented from entering just as well as by a complicated apparatus.

Dr. DELAVAN called attention to statements already made in his paper. The latter he had not intended to be a complete treatise on the subject of laryngectomy, but simply an exposition of the latest improved methods for the surgical treatment of malignant disease of the throat. It was a matter of fact that in this department distinct advances had of late been made.

**Intubation in the Adult, with Special Reference to Acute Stenosis of the Larynx.**—Dr. W. E. CASSELBERRY, of Chicago, read a paper on this subject. (See page 322.)

Dr. E. FLETCHER INGALS said: I recollect, at this moment, six cases of acute stenosis of the larynx that I have treated by intubation, and there have doubtless been others. First, a man, about fifty, with acute stenosis of a few hours' duration. The tube was introduced, but gave no relief, and the man died under chloroform administered to perform tracheotomy. Second, a woman, who possibly had diphtheria, though there was no membrane in the fauces. The tube was introduced, and remained about ten hours. I was then called to remove it, but could not because my extractor was too short. Tracheotomy was done and the patient saved. Third, a man, nineteen years of age, with acute oedema and dangerous dyspnoea. He was intubated and lived. Fourth, a woman, about twenty-two, with oedema. The tube was introduced but she coughed it out. Another physician was called in who attempted to reintroduce, but the patient died during the effort. Fifth, a man with acute oedema, in whom the tube was introduced and gave perfect relief. He lived about a week with the tube in, but coughed it out, and speedily died. Sixth, a woman with acute stenosis, in whom the tube was introduced, but gave great distress, so she was unable to wear it for any length of time. There was no permanent benefit and she died for lack of tracheotomy. In another woman in whom my tube was used, dyspnoea steadily increased and tracheotomy was attempted, but she died upon the table. My experience, therefore, has not been very favorable to intubation in acute stenosis of the larynx in adults. In introducing the tube in adults it is much better to do so by aid of the laryngeal mirror. In extracting the tube it may be very difficult to reach it by the finger, so that one needs the mirror.

In acute stenosis in adults we should not waste time on intubation, for to save the life we must nearly always do a tracheotomy later, and the earlier it is done after its necessity is established, the better.

Dr. W. K. SIMPSON, of New York, said: I think the doctor's points are well taken. We sometimes think we have an acute stenosis of the larynx, when in reality it is not so. The relief by intubation of acute stenosis produced by diphtheria and stenosis from other causes may vary considerably. In the latter instances we may have a dense underlying condition, with a superimposed acute swelling, which underlying condition may either make it very difficult to introduce the tube or entirely prevent its introduction. In the adult the tongue must be well withdrawn. It should be emphasized that where the mouth can not be well opened it is useless to try to intubate, and we should be ready to perform tracheotomy.

Dr. A. W. DE ROALDES, of New Orleans, said: I should like to call attention to a class of cases where intubation has done good, that is, in fracture of the larynx, as it holds the fragment in proper apposition.

Dr. CASSELBERRY said: The epiglottis can usually be reached by the finger with sufficient certainty to enable one to insert and extract a tube from the larynx by the sense of touch. With regard to primary oedema of the trachea, I have never seen such a case of sufficient gravity to cause dyspnoea, unless associated with chronic syphilitic stenosis of the trachea. What is termed subglottic oedema is yet in the larynx, or, at least, it involves the top of the trachea only, in conjunction with the pharynx. I did not intend to go over the whole subject of the treatment of oedema. As regards fracture of the larynx, this is covered by the part of the paper I did not read.

(To be continued.)

## ONTARIO MEDICAL ASSOCIATION.

*Sixteenth Annual Meeting, held in Windsor, on Wednesday and Thursday, June 3 and 4, 1896.*

The President, Dr. F. LE M. GRASSETT, of Toronto, in the Chair.

*(Concluded from page 847.)*

**Two Cases of Slow Pulse.**—Dr. P. A. DEWAR, of Essex, related the following cases: The first patient, a man sixty-three years of age, had had an attack of acute rheumatism fourteen years before and had apparently made a good recovery from it. Nine years later he had had some malarial affection from which he had also recovered. In 1894 Dr. Dewar had been called to see him, and had found him pale and haggard, with sighing respiration and impaired digestion. The heart beats had been strong and regular, twenty-two to the minute. On the following day they had fallen to twenty, then to eighteen, and finally to sixteen. All treatment had failed to give any benefit. This condition had lasted for two months, and since that time the patient had become epileptic. The second patient had consulted Dr. Dewar for attacks of loss of consciousness. The man had been fairly healthy, active, and strong. The pulse had been irregular and beat twenty-five to the minute. The bromide treatment had been instituted and the epileptoid attacks had become rare, but the pulse still showed little difference.

**The Treatment of Abortions.**—This was the subject of a paper by Dr. G. T. McKEOUGH in which he discussed the question from a prophylactic standpoint. Any constitutional or local cause, he said, which might possibly account for the accident should be carefully sought for. In many cases curetting or trachelorrhaphy would relieve the patient, and malarial affections, syphilis, and other disease should be treated. For periodical abortions without apparent cause asafetida and viburnum were of great value. With regard to the treatment of threatened abortion, Dr. McKeough called attention to the rationale of the morphine treatment, which, combined with rest, was a sheet anchor. The method of tamponing and of the subsequent emptying of the uterus were fully described. In about thirty cases this method had been successfully employed by Dr. McKeough, who gave an account of the important points in several of the cases.

**Amputation at the Hip Joint for Advanced Tuberculous Disease.**—Dr. ALEXANDER PRIMROSE, of Toronto, reported a number of cases, of which the following is an example: The patient, a child eleven years old, had suffered for a period of six years. There had been numerous sinuses about the hip which had discharged pus in large quantities. The apex end of the femur had been drawn up on the ilium so as to form a marked prominence below the iliac crest. The patient had been much emaciated. The liver and the spleen had been greatly enlarged and the urine had shown the presence of albumin and pus. Marked amyloid disease had been present. The time had come, said Dr. Primrose, when all such cases should be submitted to operation, for a cure was not impossible.

**The Treatment of Phthisis.**—In this paper Dr. W. B. GEIKIE referred to the prophylactic treatment and to the treatment of the patient in the pre-tuberculous stage. He spoke of the value of the various remedies which were generally prescribed after the disease had taken hold of the patient, and he drew attention to the

drugs which were best adapted for the treatment of the symptoms, such as diarrhoea and cough.

**The Treatment of Phthisis.**—Dr. HODGE, of London, stated that few medical experts of the present day would pronounce the disease incurable. He quoted Dr. Burney Yeo as saying that there were eight conditions which must exist if a cure was to be effected, the most potent of which were the early recognition of the disease, which was often favored by early hæmoptysis, and a sound organic state of the patient. Dr. Hodge stated his belief in the Koch bacillus, and said that the disease must be treated either by attacking the bacillus or by the promotion of nutrition. The latter was, in his opinion, by far the most successful treatment. A large number of phthisical patients suffered from indigestion, and he advocated a full but carefully selected diet in which the nitrogenous and fatty foods were increased and the carbohydrates diminished, as they were not easily digested by phthisical patients. He deplored the fact that some medical men advocated forced feeding, and he advised the studying of the idiosyncrasies of each patient and feeding accordingly. He did not believe in the use of alcohol, and if it was used at all it should be at meals only. Favorable nutrition of the system was also greatly aided by hygienic surroundings, such as good drainage, absence of dampness, and, above all, unrestricted fresh air.

With regard to change of climate, Dr. Hodge thought that it was cruel to send a patient away from home if the case was an advanced one. Exercise was beneficial, as a rule, as it usually involved life in the open air. Daily bathing was advocated, and underclothing which was suitable to the various seasons should be selected.

In regard to the medicinal treatment, Dr. Hodge used it for the three following purposes: 1. For nutrition. 2. To influence the virulence of the bacillus. 3. To relieve special symptoms. He had great faith in cod-liver oil as a nutritive agent, and for the second purpose he mentioned Koch's tuberculin, antitubercle serum, and antiseptics, such as creosote, which Dr. Hodge evidently considered as the true specific. He thought it ought to be given in as large doses as possible.

**Three Surgical Operations.**—Dr. T. K. HOLMES, of Chatham, reported the following cases: In the first case the operation of nephrorrhaphy had been done for floating kidney. The patient was a man of active habits, and for some years he had occasionally experienced severe pains in the stomach and in the right hypochondriac region. No gallstones had ever been found, and there had been no jaundice. There were severe dyspeptic symptoms and great emaciation, together with the most distressing pain in the abdomen. Examination revealed an enlarged right movable kidney which could be displaced beyond the median line. Nephrorrhaphy was performed by the usual lumbar incision. The capsule was incised for about three inches and stripped back to secure a fresh surface. Three silk stitches were passed through the muscles and fascia, through the denuded kidney, and again through the muscles and fascia on the opposite side of the incision. The subsequent history of this case had been favorable.

The second case was that of a woman who had been thrown from a carriage and bruised in the region of the left kidney by falling upon a stone. The operation had consisted in the removal of a renal tumor. Constant pain had ensued from the time of the injury, and about eight months afterward the patient had noticed a tumor opposite the navel on the left side. This was removed

by an abdominal incision through the linea semilunaris. The ureter and the renal vessels were tied separately, the organ was rapidly enucleated, and the whole mass was removed.

The third case was that of a young woman who had discovered a lump in the left inguinal region. It had grown to be very painful, especially at the menstrual period, and after some delay abdominal hysterectomy had been performed upon the plan suggested by Dr. Howard Kelly, of Baltimore. The tumor was found to be developed beneath the pelvic peritonæum. Symptoms of shock supervened, and eighty-four ounces of a normal salt solution were infused under each breast, and an enema consisting of two ounces of brandy in a pint of the solution was administered.

### Book Notices.

*A System of Medicine* by Many Writers. Edited by THOMAS CLIFFORD ALBUTT, M. A., M. D., LL. D., etc., Regius Professor of Physic in the University of Cambridge, etc. Volume I. New York and London: Macmillan & Company, 1896. Pp. xxxix-978. [Price, \$5.]

ALTHOUGH it must of necessity follow that a work which has such a list of contributors as this has will be of a superior order, yet in anticipation one rather underestimates than overestimates its worth. As he reads, however, he has ample evidence of the superiority of the book and perceives how unique in many respects it is. To judge from this, the first volume, it is not too much to say that it more than most works of similar compass deserves the title of system, for it is comprehensive, scientific, and systematic in the highest degree. We have before this spoken in admiration of the literary merit of many of the English medical works and have contrasted them with regret with our own, which, though scientifically their equals, are in the broad educational sense often far their inferiors. It is in this manifestation of breadth of thought and education that this volume excels, though its scientific character is not on that account the less conspicuous. The introduction, in particular, merits the warmest terms of admiration. It is written by the editor himself, and for greatness of thought, broad comprehensiveness, and beauty of language is a most able production. We wish indeed that many may read it, for the influence of such a dissertation can not but make for good.

Division I of this volume bears the title *Prolegomena*, and, as might be inferred, presents such introductory and general considerations as those on medical statistics, anthropology, heredity, medical geography, the broad fields of inflammation and of fever, the general pathology of nutrition and of neoplasms, the general principles of drug therapeutics, of climatology, of artificial aërotherapeutics, of hydrotherapeutics, of electricity, massage, and dietetics, of hygiene and nursing, and, finally, even of life insurance. It is this portion of the book which impresses us as of such unusual merit, it is so complete, so thorough, and so well expressed that we question whether its equal exists. So far as the reviewer's knowledge extends, it certainly is unrivaled.

Among articles of such unusual worth it is difficult indeed specially to commend and more difficult to criticize adversely, but we may cite the chapter upon clima-

tology as of exceeding merit, so forcibly does it present the subject and with such completeness in small space. Indeed, in many respects it excels more voluminous treatises devoted to this subject alone. On the other hand, the chapter on drug therapeutics is somewhat disappointing, and, though doubtless restricted by the space allowed, might well, we think, have been more ample.

Division II is entitled *Fevers*, and is subdivided into Parts I and II, the former upon insolation and the latter upon the infections. Insolation is well presented, though in no unusual manner, but we venture to disagree with the author in his equal recommendation of the cold bath and cold affusion. In our experience—though it is comparatively an inconsiderable one—the cold bath is generally depressing and hazardous, while sprinkling with iced water, the stream falling from a height of several feet, together with vigorous rubbing with ice, is remarkably stimulating as well as cooling, and in our hands has been incomparably the superior of the cold bath. The study of the individual infections is preceded by a most excellent chapter upon the general pathology of infection, and then are discussed, in order, septicæmia and pyæmia, erysipelas, infective endocarditis, puerperal septicæmia, furuncle, carbuncle, epidemic pneumonia, epidemic cerebrospinal meningitis, influenza (in a chapter of unusual excellence), diphtheria, tetanus, typhoid (enteric) fever, Asiatic cholera, plague, and relapsing fever.

In conclusion, we again desire to express our commendation of this volume. Doubtless those which are to follow it will be fully its equals, and in the completed work we expect to see a system of medicine which shall be unexcelled.

*The Student's Medical Dictionary.* Including all the Words and Phrases Generally Used in Medicine, with their Proper Pronunciation and Definitions. Based on Recent Medical Literature. By GEORGE M. GOULD, M. D., A. M., etc. With Elaborate Tables of the Bacilli, Micrococci, Leucomaines, Ptomaines, etc.; of the Arteries, Ganglia, Muscles, and Nerves; of Weights and Measures. Analyses of the Waters of the Mineral Springs of the United States, etc. Tenth Edition, rewritten and enlarged. Philadelphia: P. Blakiston, Son, & Co., 1896. Pp. xii-17 to 701. [Price, \$3.25.]

WE know of no medical dictionary which better fulfills the requirements of medical students than this. Its size, its typography, its contents, all combine to render it specially suitable for the purpose for which it was prepared. To be sure, we may not desire to conform to many of its orthographical requirements, especially as concerns the use of the diphthong and the employment of certain forms of termination, such as "physiologic" for physiological. Still, these are perhaps matters of preference rather than of rule, though the amputation of the terminal *e* we can not reconcile ourselves to since the letter properly affixed has long served a useful purpose in distinguishing the alkaloid from the glucoside (or perhaps we should say "glucosid") or other active principle. Matters of preference being disregarded, however, there can be nothing but admiration expressed for this volume, the usefulness of whose predecessors can not but be continued and amplified in the present edition. The tabulations, in particular, are to be commended and admired, and, so far as our observation has gone, the revision and rewriting have

resulted in completeness amply sufficient for the student of medicine. For those more advanced we can not compare it with more elaborate works, such as Dr. Gould's large dictionary.

*Clinical Diagnosis.* A Practical Handbook of Chemical and Microscopical Methods. By W. G. ARCHERSON ROBERTSON, M. D., D. Sc., F. R. C. P. E., F. R. S. E. London: The Scientific Press, Limited, 1896. Pp. 366. [Price, 6s.]

"THIS handbook," we read in the preface, "is intended to be a practical help to the student while studying clinical medicine and to the busy practitioner to whom time is of importance. Only those methods are given which the author has found easy, rapid, and reliable, neither requiring much chemical skill nor elaborate apparatus. Mere working details are stated and no theories indulged in, these not being desired by the practical investigator. Under each 'method' the diseases in which divergences from the normal may be expected are tabulated."

Such a book as this will beyond question be a great help to the diagnostician; in fact, such a work has long been needed, for, while the various matters it presents may elsewhere be obtained, they are obtainable only from a multitude of sources. Aside from the rich inclusiveness of the book, the brief and terse character of its contents is a great advantage. The physician indeed who seeks a test must know that it is reliable, but for the multitude of theories which may more or less closely pertain to it he cares little. As an aid to the clinician we must rank this work most high and can give to it our unqualified approbation.

*Practical Points in Nursing.* For Nurses in Private Practice. With an Appendix containing Rules for Feeding the Sick; Recipes for Invalid Foods and Beverages; Weights and Measures; Dose List; and a Full Glossary of Medical Terms and Nursing Treatment. By EMILY A. M. STONEY, Superintendent of the Training School for Nurses, Carney Hospital, South Boston, Mass. Illustrated with Seventy-three Engravings in the Text and Nine Colored and Half-tone Plates. Philadelphia: W. B. Saunders, 1896. Pp. 12 to 456. [Price, \$1.75.]

THIS book is a brilliant and striking example of the class which a little knowledge makes dangerous, because it aims to teach too much and therefore teaches unwisely; but chiefly because its author would seem not to have confined herself to the sphere in which she is evidently accomplished as a teacher, but has sought to include much that is beyond her. "Practical points in nursing" may describe the scope of the work to a certain extent, but one should know that the book aims to teach not only nursing, but also anatomy, physiology, the practice of medicine, obstetrics, gynecology, and poatology—all viewed, it is true, with the eyes of the nurse, but viewed through the glasses of the practitioner, which, to be homely, the nurse has no business to have on. Nurses no doubt pick up much that is medical from their intercourse with physicians and their observation of cases, but the best nurse is she who keeps the greater part of this knowledge to herself and does not seek to ape the practitioner. Frankly, therefore, we think that were a nurse to imitate the teachings of this book and to act on them (as she probably would, for nurses are not apt to be secretive of their medical know-

ledge) she would probably effect the resignation of the physician in attendance or her own.

So far as the "points" which treat of nursing pure and simple go, the book is excellent, but beyond this it is bad without qualification, bad not only in quantity but in quality. The instances of these failings are many, and, while some are rather errors of expression than errors of fact, they are not on that account the less erroneous. Inflammation is described in about a page and a half, and the description is remarkable for a highly original presentation of the phenomena of clotting and the startling statement that the redness of inflamed tissues is "due to increased hematin in the blood of the part." Then, too, we are told that if inflammation continues "it generally terminates in an abscess," and forthwith is introduced the poultice to bring it "to a head." The vexed problem of the action of counter-irritants is solved by the writer; they act "by irritating the ends of the sensory nerves and dilating the blood-vessels of the part so that the circulation of the blood through them is increased; the blood is brought to the surface, thus relieving the inflamed part beneath." This quite disregards the possible non-existence of a vascular connection between the parts. The writer demands that in obtaining the morning specimen of urine it be drawn with a glass catheter. This, no doubt, may often be necessary in obstetric practice, but may not urinary examinations be necessary in other conditions (possibly in male patients), and is not voluntary micturition permissible?

To delay sending for the physician until (in labor) "the bag of waters breaks" is scarcely sound advice, we think, but it is not the least of the crudities the obstetric portion of the book contains. To attribute typhoid infection to "bad air," too, in these days is going too far, and to emphasize the danger one incurs by attending a case of tuberculosis when cuts or scratches exist upon one's hands is ill-advised in view of the extreme rarity of constitutional infection thereby ("germs entering the body through the broken skin"). Kissing, though delectable, it seems is not permissible in pulmonary tuberculosis. We were so inclined to believe, though we were not aware that the prohibition was altogether due to the possibility of infection "transmitted by sores that may be on the lips."

"Angina pectoris is neuralgia of the heart: the patient has severe pain around the heart and there is difficult breathing. Hot alcoholic stimulants should be given and heat applied over the heart." So much for angina pectoris. The causes of gastritis, according to the writer, are imperfect mastication of the food, drinking liquid too hot or too cold, and drinking any of the corrosive or irritant poisons. That is all. The symptoms of gastritis, however, include "all the symptoms of collapse." Incidentally, the distended bladder must not be emptied suddenly by catheter, lest the walls of the bladder fall together and cause cystitis! We do not wish to seem difficult to please, but these things are among the features of the book which we regard as unusual.

As we have said before, however, the portions of the book which are devoted to nursing in its true and proper sense are excellent and reliable. Among them none is better than the chapter on feeding the sick, for this, with its excellent recipes and its thoroughly practical character, is a thing to be commended. If our comments are severe we have some regret, for we do not wish to discourage, and indeed there is much to applaud, but we heartily disapprove of the type of book of

which this is an example. Finally, we can not but note the orthography which ornaments this work; witness "tincture of iodine," "oxid of zinc," "peroxid of hydrogen," "morphine," and "gynecologic." The book-making is excellent.

#### BOOKS, ETC., RECEIVED.

A Treatise on Appendicitis. By John B. Deaver, M. D., Surgeon to the German Hospital, Philadelphia. Containing Thirty-two Full-page Plates and other Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1896. Pp. xv-17 to 168. [Price, \$3.50.]

Die Mikrotechnik der thierischen Morphologie. Eine kritische Darstellung der mikroskopischen Untersuchungsmethoden. Von Dr. med. Stefan Apathy, Professor der Zoologie und vergleichenden Anatomie an der Universität Kolozsvár. Erste Abtheilung. Mit 10 Abbildungen in Holzschnitt. Braunschweig: Harald Bruhn, 1896. Pp. 322.

The Mulum in Parvo Reference and Dose Book. By C. Henri Leonard, A. M., M. D., Professor of the Medical and Surgical Diseases of Women, etc. Detroit: The Illustrated Medical Journal Company, 1896. Pp. 144.

Eighteenth Annual Report of the State Board of Health of the State of Illinois. For the Year ending December 31, 1895.

Proceedings of the Eighth Annual Session of the Association of American Anatomists, held in Philadelphia, December 27 and 28, 1895.

Report of the Bureau of Health of the City of Denver. For the Year 1895.

Operations Performed in the Eye Department of the Medico-chirurgical Hospital. By Dr. L. Webster Fox, of Philadelphia. [Reprinted from the *Ophthalmic Record*.]

Polyorchidism. By Dr. D. S. Lamb, of Washington. [Reprinted from the *Proceedings of the Association of American Anatomists*.]

Ophthalmia Neonatorum. By William Cheatham, M. D., of Louisville, Ky. [Reprinted from the *Virginia Semi-monthly*.]

Casts of the Uriniferous Tubules. By Thomas B. Carpenter, M. D., of Buffalo. [Reprinted from the *Buffalo Medical Journal*.]

The Management and Treatment of Tuberculosis in the Asheville Climate. By James A. Burroughs, M. D., of Asheville, N. C. [Reprinted from the *North Carolina Medical Journal*.]

A Concluding Report of the Anatomy of the Elephant's Ear. By Huntington Richards, M. D. [Reprinted from the *Transactions of the American Otological Society*.]

An Uninterrupted Stitch by a Continuous Method. By Campbell Ford, M. D., of San Francisco. [Reprinted from the *Pacific Medical Journal*.]

Hypnotic Suggestion as a Cure for Asthma. By Thomas Bassett Keyes, M. D., of Chicago. [Reprinted from the *Medical World*.]

The Clinical Examination of Deaf-Mutes. By S. T. Walker, M. D., of Jacksonville, Ill. [Reprinted from the *Cincinnati Lancet-Clinic*.]

Temporary Abulic Agraphia probably Due to Partial Obstruction of the Superior Longitudinal Sinus. By J. T. Eskridge, M. D., of Denver. [Reprinted from the *Colorado Medical Journal*.]

Implantation of a Glass Ball in the Orbit after Enucleation of an Eye. By L. Webster Fox, M. D.

Valedictory Address to the Graduating Class of the Medico-chirurgical College of Philadelphia. By L. Webster Fox, M. D. [Reprinted from the *Medical Bulletin*.]

Twentieth Century Practice. An International Encyclopædia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M. D. In Twenty Volumes. Volume VIII. Diseases of the Digestive Organs. New York: William Wood and Company, 1896. Pp. 2 to 667.

Deformities. A Treatise on Orthopædic Surgery. Intended for Practitioners and Advanced Students. By A. H. Tubby, M. S. Lond., F. R. C. S. Eng., Surgeon to the National Orthopædic Hospital, etc. Illustrated with 15 Plates and 302 Figures, of which 200 are Original, and by Notes of 100 Cases. London and New York: Macmillan & Co., 1896. Pp. xxii-3 to 598. [Price, \$5.50.]

A Treatise on Surgery. By American Authors. For Students and Practitioners of Surgery and Medicine. Edited by Roswell Park, A. M., M. D., Professor of the Principles and Practice of Surgery and of Clinical Surgery in the Medical Department of the University of Buffalo, Buffalo, N. Y., etc. Volume I. General Surgery. With 356 Engravings and 21 Full-page Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. 6 to 799. [Price, \$4.50.]

Diet for the Sick. Contributed by Miss E. Hibbard, Principal of Nurses' Training School, Grace Hospital, Detroit, and Mrs. Emma Drant, Matron of Michigan College of Medicine Hospital, Detroit. To which have been added Complete Diet Tables for Various Diseases and Conditions as given by the Highest Authorities. Second Edition, revised and enlarged. Detroit: The Illustrated Medical Journal Co., 1896. Pp. 5 to 103. [Price, 25 cents.]

The American Academy of Railway Surgeons. Report of the Second Annual Meeting, held at Chicago, Ill., September 25, 26, and 27, 1895.

Twentieth Year-book of the N. Y. S. Reformatory, for the Fiscal Year ending September 30, 1895. With Illustrations and Anthropometric Tables.

So-called Epispadias in Woman, with an Illustrative Case. By J. W. Ballantyne, M. D., Edinburgh. [Reprinted from Volume Fourth of the *Edinburgh Hospital Reports*.]

Tylosis Palmæ et Plantæ, with the Description of Two Cases, Mother and Daughter. By J. W. Ballantyne, M. D., and George Elder, M. B., Edinburgh. [Reprinted from *Pædiatrics*.]

Arteriosclerosis among the Insane. By E. D. Bondurant, M. D., Tuscaloosa, Ala. [Reprinted from the *International Medical Magazine*.]

Modern Methods of Treatment of Typhoid Fever Critically Reviewed, with Suggestions for a Rational Therapeutics. By Gustavus M. Blech, M. D., Detroit. [Reprinted from the *Journal of the American Medical Association*.]

Some Conclusions Drawn from Experiences in Pelvic Surgery. By A. V. L. Brokaw, M. D., St. Louis. [Reprinted from the *Medical Mirror*.]

The Paroccipital Fissure. Should it be Recognized and so Designated? By B. G. Wilder, M. D., Ithaca. [Reprinted from the *Proceedings of the Association of American Anatomists*.]

Exhibition of a Suicide's Brain. By Burt G. Wilder, M. D. [Reprinted from the *Journal of Nervous and Mental Diseases*.]

The Cerebral Fissures of Two Philosophers. Chauncey Wright and James Edward Oliver. By Burt G.

Wilder, M. D. [Reprinted from the *Journal of Comparative Neurology*.]

Periodische Depressionszustände und ihre Pathogenese auf dem Boden der Harnsauren Diathese. Von Professor C. Lange, in Kopenhagen. Autorisirte deutsche Ausgabe nach der zweiten Auflage des Originals. Von Dr. Hans Kurella. Hamburg und Leipzig: Leopold Voss, 1896. Pp. 7 to 55.

## New Inventions, etc.

### A HAWKBILL NASAL SCISSORS.

By JOHN C. LESTER, A. M., M. D.,

BROOKLYN, N. Y.,

ASSISTANT SURGEON, ST. BARTHOLOMEW'S CLINIC FOR DISEASES OF THE EYE, EAR, THROAT, AND NOSE; ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY; ASSISTANT TO THE CHAIR OF OTOLGY, BELLEVUE HOSPITAL MEDICAL COLLEGE, ETC.

The hawkbill scissors, illustrated below, will be readily recognized as an adaptation of an idea long since put into practical application by Professor Alexander J. C. Skene, of this city, in another department of surgery.

In operating upon cases of hypertrophy of the middle turbinated bone, the thought occurred to the writer that a more rapid and perhaps more satisfactory method of dealing with this condition might be accomplished by an instrument that would remove a V-shaped piece of the bone, thus allowing the major part of the mucous membrane to remain intact, and providing, when the remaining cut surfaces were brought together, a space sufficient-

ly large for perfect respiration. This thought has materialized in the device herewith presented.

The idea of removing the middle third of the turbinated bone, and allowing the opposing portions to unite, thereby retaining as much of the mucous membrane as possible, originated with Dr. Fred. Whiting, of New York city, and was accomplished by means of the nasal trephine. This method of operating, in the hands of the writer, has, almost without exception, caused much pain, and at times it has been necessary to postpone operation, owing to excessive hemorrhage.

With these scissors the writer has been able to remove at once all that was necessary to relieve cases of complete obstruction.

The accompanying cut, kindly furnished by the instrument-makers, Messrs. George Tiemann & Co., accurately represents the instrument as employed by the writer.

## Miscellany.

**The Treatment of Animals Poisoned with Snake Venom by the Injection of Antitoxic Serum.**—In the *British Medical Journal* for August 15th we find an abstract of a lecture by Dr. A. Calmette, of the Pasteur Institute, Lille. The importance of the treatment of snake bite is of great importance, he says, in connection with the Indian, Burmah, Australian, and African colonies, as in India alone there are annually between twenty and thirty thousand deaths from snake bite, while the financial loss by the death of cattle, due to the same cause, is very considerable. For this reason it is obvious that any treatment of snake bite which offers reasonable promise of diminishing this mortality should be seriously considered by those who are responsible for the health administration of districts in which snakes are found.

For some time past the author has devoted considerable attention to the production of antitoxic serum, and after many experiments he succeeded some time ago in placing in the hands of physicians in India and Australia a serum the value of which has now been proved in a small number of cases in which the snake which bit the patient has been identified and captured. Many of his observations, he says, have been confirmed, some by Professor Fraser, others by observers in British colonies, but the importance of the serum method of treatment has even now not been fully realized.

These experiments are easily carried out, and are absolutely painless; in rabbits, as in the case of the human subject, the first symptom indicating the action of snake poison is slight somnolence, which, becoming more and more marked, is gradually succeeded by a condition of unconsciousness associated, first, with muscular contraction, and then with loss of motor power, which, beginning in the hind limbs, passes forward until the respiratory centres are affected, the cardiac centre being the last attacked. When the animal dies the heart is found in a condition of diastole. The venom may be injected in two ways—intravenously, when a comparatively small dose acts with great rapidity; subcutaneously, when the dose also acts powerfully, but more slowly. A lethal dose of cobra poison injected subcutaneously is about a milligramme of dried substance, which proves lethal in about twelve hours. Twice

this quantity, injected into the veins, kills a rabbit of about 1,500 grammes in sixteen minutes. Five times as much, introduced subcutaneously, proves fatal in about three hours and a half.

With regard to the protective injections, says Dr. Calmette, there is ample evidence of the great protective power that this serum exerts when it is injected before the venom is introduced, of which the following is an example: Four rabbits were injected in the lateral aural vein each with three cubic centimetres of the antitoxic serum, and some time afterward two milligrammes of dissolved dried venom were injected; this was a sufficient quantity to kill the animals in sixteen or seventeen minutes, but none of the animals showed any symptoms of sleepiness, and it was evident that the venom had little if any effect upon them. On the other hand, two cheek rabbits were each injected with two milligrammes of the venom, and they both succumbed in about seventeen minutes.

To show the curative properties of the serum, experiments were made in which some rabbits received five milligrammes of the venom under the skin. Half an hour afterward two of the animals received three cubic centimetres of the serum, and they showed no symptoms of poisoning and remained perfectly well. In an hour after the venom had been introduced two other animals received the serum and they also remained well. Two more rabbits should have been left for an hour and a half, but the dose of poison was so large that one of the animals died at the end of an hour and twenty minutes; the other animal was immediately injected with the same dose of serum with the result that it became well. This, says the author, is a very striking proof of the efficacy of the serum.

Although the serum does not act directly upon the toxine, but only through the cells, it begins to exert its influence immediately it is introduced into the body. This fact is well brought out by the following experiments: Three cubic centimetres of the serum were injected into the lateral vein of the left ear of a rabbit weighing 1,280 grammes; fifteen minutes later this animal received into the lateral vein of the right ear two milligrammes of the venom (sufficient to kill it in less than twenty minutes had it not received the serum); the animal has remained perfectly well, and still shows no evidence of poisoning by snake venom. A more striking experiment still is the following: A rabbit having received intravenously two milligrammes of venom, two minutes later was injected with five cubic centimetres of the serum in the vein of the opposite ear. The animal has remained perfectly well. Such an experiment shows that the venom does not destroy the cellular elements at once, and that even when the poison has already found its way into the circulation these cells may be rendered insensible to the action of the poison by means of the action of the serum.

Dr. Calmette thinks that the use of this serum must necessarily become generalized at no distant date in all countries where venomous snakes are found, in order that both men and domestic animals may be protected. Is it not advisable, therefore, he asks, for the British or Colonial Governments, which are deeply interested in this matter, to take rigorous measures in order to prevent the sale in England and in its colonies of serums for which no absolute guarantee of efficacy and purity is given?

He proposes the adoption of the following resolutions, and that they should be brought in some way before the Government at as early a date as possible:

1. That there shall be instituted in London and in each British colony where there are found venomous snakes a sanitary committee to be intrusted with the duty of testing the efficacy of serums offered for sale or sent out to be delivered gratuitously by druggists and others.

2. That no bottle shall be sold or distributed unless bearing the mark of such control.

3. That this control shall be effected according to the sole simple and rapid method which presents every guarantee of accuracy.

4. The method proposed is the following: A standard solution of type venom will be placed at the disposal of the appointed experts. The toxic unit of this solution will be based on the quantity of venom necessary to kill a rabbit of two kilogrammes in twenty minutes by intravenous inoculation in the marginal vein of the ear; this quantity corresponding on an average to two milligrammes of cobra venom (weighed dry) and to four

milligrammes of rattlesnake venom. An antitoxic serum, to be sufficiently active for therapeutic use, must be a preservative in a minimum dose of two cubic centimetres on intravenous injection into a rabbit of two kilogrammes against an intravenous injection of the toxic unit of venom. The preventive inoculation must be made fifteen minutes only before the inoculation of the venom. The testing of the serum is thus effected in less than half an hour.

5. That stations provided with serum and all the necessary apparatus for its application shall be established in the principal centres of agriculture and in the mining and forest districts of the colonies infested with venomous snakes, such as Australia, Burmah, and India, so that every person bitten may be able to come at once and receive treatment.

**Serum Treatment in Tuberculosis.**—At the recent meeting of the American Medical Association Dr. Paul Paquin delivered an interesting report on the treatment of tuberculosis by serum, of which the following is an abstract from the *Journal of the American Medical Association*: There are some, says Dr. Paquin, who have failed in treating consumption with serum; there are physicians who have doubts as to its value in therapeutics except that which may be due to inherent conditions dependent on the relative immunity of the horse against tuberculosis; doctors who doubt the qualifications of private laboratories and their workers, and of a general practitioner's ability, opportunities, and time to investigate, and to experiment scientifically, safely, and successfully.

The antitubercle serum, like the antitoxine for diphtheria, rests on the biological laws governing the defensive forces of an organism to oppose the encroachment of microbes and their products on the tissues and blood. Tuberculous individuals sometimes recover without a remedy. This is due to Nature's own efforts—viz., exalted phagocytosis, with all that this interesting physiological phenomenon implies. A complex being, such as man or the horse, is a republic of small animated subjects, the cells, with distinctive individual properties and obligated to co-operative functions for the sustenance of the whole. The brain and nerve cells constitute the governing power; the phagocytes constitute the soldiers of the country. Their arms consist of their individual annihilating power in a physical sense and the antitoxine elements they produce, capable (probably by a digestive or diastatic property) of neutralizing the poisons thrown amidst them by the armies of microbes constantly attacking the wonderful aggregations which they defend. What occurs in a case of consumption cured by Nature occurs in a horse properly subjected to the influence of the consumption poison. Either a natural antidote is increased in power, or a new one created, and this, says Dr. Paquin, is what exists in the serum he uses in man. Man suffering from tuberculosis is under the influence of a certain amount of tuberculin, a poison, and Nature produces in his system an antitoxine to counteract this noxious agent. But usually the army of invaders win the fight after a more or less prolonged and painful conflict. What the laboratory is expected to do is, to supply man with this defensive force, the antitoxine produced at the expense of the horse's system rather than his own.

One must not be too sanguine, he continues. Little hope can be offered to the unfortunate who suffers from advanced tuberculosis, with extensive destruction

of tissue; general tuberculous intoxication; general debility; pronounced dyspepsia, deficient assimilation and dissimulation, difficult and perverted secretions and excretions, and the hopelessness of such cases is emphasized, more or less, according to the more or less pronounced microbial complications which may exist. These complications, he says, are influenced only secondarily, by virtue of Nature having recovered some strength after the bacilli of tuberculosis are arrested in their development and devastation. He has confidence that early cases of tuberculosis can nearly all be arrested by serum administered under proper conditions, and that were it the policy of the laity to submit to constant observations and repeated analysis the moment a lung or bronchial irritation manifests itself, the diagnosis of incipient phthisis would be made early enough to diminish the death-rate due to consumption ninety per cent. by the action of serum.

Dr. Paquin calls attention to cases that have not yet been reported, or reported in the past to a limited degree, in which the patients are now in a different or more improved condition. The results obtained, he says, have been favorable and unlooked for; the patients have regained their health and strength and have resumed their regular occupation. With one exception there was a remarkable increase in weight and a wonderful improvement in the condition of the lungs.

The favorable effects of the serum treatment, however, says Dr. Paquin, must not be overestimated, for improvement in cases of very advanced disorganization and prostration has not been of long duration, as this treatment can not be expected to replace lost tissue or cure fatal lesions. It is, therefore, of radical and great importance to diagnose tuberculosis at the earliest possible moment, before a too grave mixed infection takes place.

**Nucleins and Nucleoproteids in their Relation to Internal Secretion.**—In the *Boston Medical and Surgical Journal* for August 20th there is an article on this subject by Professor Russell H. Chittenden in which he remarks that the internal secretion of glands is rapidly becoming a subject of primary importance to the physiologist, and its development bids fair eventually to furnish the physician with a fund of knowledge directly applicable to the explanation of many obscure disorders, and replete with suggestions as to methods of treatment. Until quite recently, he says, the more prominent secreting glands and structures of the body have been associated solely with their obvious function of manufacturing a specific secretion or excretion to be discharged externally through special conducting tubes. The existence of so-called ductless glands, however, such as the suprarenals, thyroid, thymus, etc., with cellular structure bearing all the marks of active tissue, has long pointed to the probable production in such glands of specific secretions designed solely for internal use—namely, the manufacture of substances which may be at once resorbed into the blood, and perhaps utilized in a variety of ways for controlling and regulating either special or general metabolism.

It is not Professor Chittenden's purpose to enter into detail concerning our knowledge of the internal secretions formed by the liver, kidneys, thyroid, pituitary body, suprarenals, etc., but he emphasizes the fact that information already accumulated shows plainly that all of these glands are active in the formation of internal secretions, all of which are endowed with marked physio-

logical properties. He thinks that this metabolic activity, characteristic of these several glands results, in some cases, in the formation of several physiologically active substances, some of greater importance than others.

The production of the specific substances which give character to the various internal secretions is obviously a function either of special cells contained in the gland, or it may be in some cases an inherent quality of all the cellular elements of a given gland.

However specialized the cells concerned in the production of these physiologically active substances may be, he continues, they are certainly typical cells with distinct nuclear protoplasm and cytoplasm, and if one is to unravel the nature of the chemical processes by which the active agents are produced and learn their true origin, as well as their exact chemical structure, it becomes necessary to study the character of the material of which the cells are composed, and out of which the physiologically active principles are constructed. It is quite proper to say that these bodies originate through the metabolic activity of the cell, but such a statement carries with it little exact knowledge and throws little light upon either the nature of the process or the character of the resultant products. Further, we must not limit our conception of internal secretion to a few isolated glands, but keep clearly in mind the fact that wherever there is metabolic activity absorption of products is likely to occur, and is, no doubt, a constant feature of all glands and tissues, although obviously not all organs yield catabolic products of vital importance.

A few years ago, says the author, our knowledge of these bodies was very limited—and indeed it is none too complete to-day—but recently it has been growing very rapidly and we are learning that under the name of nucleoproteids, nuclealbumins, nucleins, and nucleic acids we have to deal with a class of very remarkable bodies which constitute the greater part of the nucleus and cytoplasm of nearly all cells, and which evidently play an all-important part in every form of cell metabolism. Proteid or albuminous bodies have long been known as the chief constituents of protoplasm, but we now understand that it is not as simple proteids that these bodies exist in the cell, but mainly as compound bodies—that is, as combinations of nucleic acid with some form of proteid or albuminous matter.

Between the cytoplasm and caryoplasm of a cell the cytologist recognizes a distinct and usually constant difference, which shows itself at once on the application of appropriate dyes. The nucleus of the cell is rich in nuclein, while the cytoplasm, and perhaps the nucleoli as well, are characterized by the presence of nuclealbumin with a less marked affinity for dyes. But nucleins and nuclealbumins or nucleoproteids differ from each other simply in the proportion of proteid and nucleic acid which they contain. The bodies of this class are all acid bodies, of weak acidity to be sure, and with a varying degree of acidity, but sufficiently marked in every case to suggest the presence of some form of acid radicals. This fact, indeed, says Professor Chittenden, led to the discovery of nucleic acids, bodies readily obtainable from all forms of true nucleins by the action of dilute alkalis, the latter seeming to break up the combination existing between the acid and the albuminous matter with which it is naturally combined. A so-called nuclein is thus seen to be simply a combination of some form of proteid matter with a nucleic acid, while a true nucleoproteid or nuclealbumin is a combination of a nuclein with more albuminous matter.

Another fact which implies the existence of even a greater variety of nucleic acids is found in the presence of carbohydrate groups in some acids. Thus, the nucleic acids obtainable from the cells of the pancreatic and mammary glands, as well as those prepared from yeast cells, yield by cleavage a reducing carbohydrate, while from the acid of the thymus gland levulinic acid has been obtained. In some other forms of nucleic acid, on the other hand, no carbohydrate groups can be detected. Again, there are some forms of nucleic acid, so-called paranucleic acid, from which no nucleic bases whatever can be obtained by decomposition. Hence, says Professor Chittenden, it is very evident that under the head of nucleic acids there is a large class of closely related bodies, superficially showing a close resemblance in general reactions and properties, but with a diversity in inner structure clearly suggestive of corresponding differences of function.

The very nature of the many bases which come from the cleavage of the nucleic acids outside of the body; the ready convertibility of these bases into other allied bodies by oxidation and reduction; their own physiological action, which though mild is marked; the possibility, the probability, that many other catabolic products may be obtained from these nucleic acids; and further, that still other nucleic acids, at present undiscovered, may exist in the cell protoplasm; all offer good reasons for believing that the nucleins and nucleoproteids, which are the most prominent constituents of the protoplasm of all cells, are the most probable antecedents of the internal secretions.

**Modern Greek as the Language of Science.**—An Athenian newspaper, the *Kafoi*, prints the following remarks introductory to a translation of Dr. Achilles Rose's lecture given at the Academy of Medicine a few weeks ago:

Efforts are being made in America to do away with the Erasmian pronunciation. The *Ἀρχαῖς* (the Greek journal of New York) and the patriotic Professor Leotsakos started the fight in the American periodicals, but the true apostle, the ardent and zealous defender of our true and historical pronunciation and language in the New World, is the distinguished American physician and Hellenist, Dr. Achilles Rose. This learned and indefatigable Philhellene, who has promoted a better knowledge of living Greek by his writings and lectures, who by his arguments, which could not be contradicted, has upheld the true Greek pronunciation, has at the same time undertaken the herculean work of advocating Greek as the international language of science. We deem it our duty to make known to the Greek public the profound and scholarly lecture published in the *New York Medical Journal*, which lecture gives a study of the historical evolution of the Greek language and the various phases through which it has passed. This lecture, of which the following is a translation, was delivered recently in New York before a numerous and select gathering, was loudly applauded, and after having appeared in print was highly appreciated by American scholars.

**Transportation Arrangements for the Mexican Meeting of the Pan-American Medical Congress.**—The secretary of the international executive committee, Dr. Charles A. L. Reed, of Cincinnati, informs us that Dr. H. L. E. Johnson, of No. 1400 L Street, N. W., Washington, has been elected chairman of the special committee on transportation. All communications relative to rates,

reservation in the special trains, etc., should be addressed to him. A rate of one fare for the round trip has been secured between St. Louis, New Orleans, and other trans-Mississippi points, and the City of Mexico. It is confidently expected that this rate will be extended over the entire territory of the United States. Arrangements are in progress for a splendidly equipped train of sleeping and observation cars, with first-class dining-car service. Dr. Johnson will presently be able to announce a rate which will include railroad fare, sleeping and dining-car service both ways and in the City of Mexico, covering also the expense of various side trips to the most important historic points in the Republic.

**Unguentum Resinol.**—According to Dr. Robert C. Kenner, of Chicago (*Medical Progress*, August, 1896), this preparation is very serviceable in allaying the pain and itching of hæmorrhoids, also pruritus and irritation of the skin.

**The Power of Sentiment.**—The following is taken from a very interesting address delivered by Lieutenant-Colonel Alfred A. Woodhull, of the medical corps of the army, to the graduating class of the Medical Department of the University of Colorado, on June 3d, and published in the August number of the *Colorado Medical Journal*:

At the great battle of Antietam, fought in 1862 to preserve the "more perfect union" on the anniversary of the adoption of the constitution that created that union, the 17th of September, it was my lot to view a part of the field that at the time was comparatively clear. In the central foreground was a body of infantry in line of battle that had advanced firing, until halted by a foe invisible from my more elevated station. The course of the advance was marked by blue blots upon the sunburnt field. From the firing line by ones and twos slowly retiring forms passed to the rear. These motionless and straggling figures were the sparks struck by the friction of war from the advancing force, as a meteor leaves its fiery trail in the sky above. As I looked, the advance became more difficult; more maimed men dropped, out or lay stretched in their final rest. The progress was slower; the battalions failed to move forward. Under the fire of a yet unseen foe, whose execution improved as the distance diminished, the casualties increased. I could at last see the line begin to waver, a tremor ran through it, an undulation as in a vibrating rope, and I feared that it would bend before the leaden rain, bend and disintegrate. But just as the tremor was at its height an officer seized a flag, ran forward twenty or thirty yards across the field, and planted the staff as a goal. Immediately and spontaneously the line moved forward and dressed upon the colors, and at the instant the hitherto invisible foe arose from a sunken road and a dust-gray cloud floated backward as our people advanced to the position that had been so obstinately defended. The flag of the Union had waved its silent appeal to the troops of the Union; the wavering line responded to sentiment, and there was a new illustration of its efficient force.

Perhaps—I hope not—all this seems to you irrelevant. You are about to become doctors, not soldiers. Incidents of the sulphurous field point no moral for your quiet life. I beg you to take no contracted view. I am speaking to you as men and not as doctors, not as any class hampered with regular pursuits, secular or domestic. The heroic examples just cited are but one phase of life, indeed only one phase of heroism. It by

no means follows, because we can not all build palaces for the great of the earth to share our magnificence, that we must live in humble cottages, or, tentless, bivouac by the wayside. For humanity, standing a little lower than the angels, is many sided and my warning to-day is directed against concentrating your energy upon the material, to the exclusion or suppression of the incorporeal features of life.

**Medical Education in the United States.**—The United States Bureau of Education has issued a report concerning professional education in the United States, of a portion of which the following is an abstract:

The students in regular medical schools in 1883-'84 numbered 10,600; in 1893-'94 they numbered 17,601, an increase of sixty-six per cent. Students in homœopathic schools in 1883-'84 were 1,267; in 1893-'94, 1,666, an increase of 31.5 per cent. The eclectic students numbered about the same at the two periods—1,611 in 1883-'84, and 803 in 1893-'94, an increase of only 4.7 per cent. The number of regular medical students increased more than twice as fast as homœopathic students, and more than fourteen times as fast as the eclectics.

If this increase in medical students continues, the question will soon be raised, What are they all to do? Where can so many find places to practise their profession?

It is no wonder that medical men complain of hard times when competition must necessarily be so keen. It is presumed that a rather large percentage of American medical students fall by the wayside, or, if they graduate, fail to pursue their profession. It is at best hard to understand how 8,000 new doctors every year can earn a living. It is, in fact, becoming constantly harder for a young medical man to get a foothold. What he lacks in training at college he makes up by long waiting after he gets his degree.

The ratio of medical students to population in the United States is about twice what it is in European countries. The following statistics from the *Journal of the American Medical Association*, January 12, 1895, give an exhibit of different countries:

"United Kingdom (Great Britain and Ireland), 8,696 total registered medical students between 1889 and 1893; for the year 1893, based on yearly accretions, 7,000; population, 37,000,000.

"France, total number medical students inscribed on the books of the Paris Faculty of Medicine for 1894, 5,144; population, 40,000,000.

"Germany, total number medical students registered for 1894, 8,684; population, 50,000,000.

"United States and Canada, total number medical students in attendance in 1891, 20,800; population, 79,000,000.

"Proportions: In the United Kingdom, 1 medical student to 5,286 of population; in France, 1 to 7,776 of population; in Germany, 1 to 5,757 of population; in the United States and Canada, 1 to 3,365 of population."

If these figures were even only approximately correct, the medical profession is sure to be even more crowded than it is at present, and it has been found that raising the standard both for entrance and graduation has not diminished the actual number in attendance, however many it may have kept out. But the question may be asked, Is it, after all, surprising that the medical profession is crowded? What profession or trade is there which is not crowded? And is it not but natural that the professions here have larger numbers in propor-

tion to population than in European countries? The common schools and public high schools are educating large numbers of young men who have aspirations for the higher callings, and a larger number of parents in this country can gratify such desires than would be possible in densely populated Europe. It would not be a credit to American youths if, after enjoying a high-school education or even a full common-school education, they should be content to engage in work calling for no thought. While digging out coal or iron is honorable work, and the industrious and honest miner deserves every respect, it is nevertheless true that if a young man contents himself with this work, who has received good home training and has enjoyed the privilege of completing a full course in a common school and a public high school, and who is able to discharge successfully the duties of positions of trust and responsibility requiring good educational qualifications, he falls far short of filling the place for which he was prepared; he makes a poor recompense for the care, attention, and expense which were bestowed upon him; while his work is honorable, he deserves dishonor. Young men who have enjoyed good educational advantages know that they must make proper use of them, and as so many in this country receive such training it is not surprising that candidates for professional life are numerous.

But it need not be expected that all young men who can pass the final examination in medical colleges and the State examinations will have those other qualifications—perseverance, fortitude, etc.—which must be exercised so largely in attaining practical success in medicine. Some competitors must fall by the way. The law of the survival of the fittest must hold in medicine as in other pursuits. Large numbers of young men, after graduation in medicine, find openings in other lines which yield an immediate income, and others find that while the study of medicine is pleasant, to them the practise of it is very different.

In the statistical tables of 1893-'94 there are in all 152 medical schools: 109 regular, 19 homœopathic, 9 eclectic, 3 physiomedical, 2 preparatory, and 10 graduate. Omitting the preparatory and graduate schools, which are non-scholastic, there are in the regular schools 17,601 students—about eighty-seven per cent. of the whole number. In the eclectic, homœopathic, and physiomedical schools there are 2,561—about thirteen per cent.

In a few universities there is a course designed to be preparatory to regular medical work and taking the place of the first year medical course. In some other institutions a course is provided for post-graduate medical work. The course preparatory to medicine includes subjects usually taught during the first year in medical colleges having graded courses of three or four years—chemistry, anatomy, physiology, botany, and materia medica.

In the University of Kansas there is a preparatory medical course to which any student can be admitted who is prepared for entrance to the freshman class of the school of arts in all English studies. There are two terms of twenty weeks each. Students completing the work are admitted to the second year's course in any of the larger medical colleges. During the year 1894 property to the value of \$100,000 was given for the development of the medical department.

In Brown University, Rhode Island, a course of studies has been selected as suitable for students preparing for the medical profession.

Randolph Macon College, Virginia, and Nebraska State University also have courses preparatory to medicine.

Clark University, Worcester, Massachusetts, has a department where graduates in medicine and college graduates can pursue the study of the purely scientific branches of medicine, such as chemistry, biology, psychology, and anthropology. The department affords no opportunities for dissection or hospital work, and does not confer the degree of M. D.

In the University of Pennsylvania the auxiliary faculty of medicine supplements the customary course of medical instruction by lectures on branches of science essential to the thorough education of the physician. The course is essentially post-graduate. There can be no matriculation by medical students until the student has entered upon his second year of medical study.

A student in the auxiliary department of medicine who is a baccalaureate graduate in arts or science of this university or of an American college whose degrees are accepted by this university as equivalent to its own may become a candidate for the degree of doctor of philosophy on fulfilling certain requirements prescribed by the faculty of philosophy of the university. He may choose his three required subjects from the following studies: Botany, zoology, geology, mineralogy, and bacteriological hygiene.

It is noticeable that if one or two border States are omitted there are no homœopathic students in the South. In the North Atlantic States there are 595 homœopathic students; in the North Central there are 958; but in the South Atlantic and South Central combined there are only 61, and these are in the border cities, Baltimore, Washington, and Louisville.

There are always quite a number of women engaged in the study of medicine. Most of these probably enter upon a general practice, while others seek a practice specially among women and children. Judging from the enrollment of women students, homœopathy and eclecticism seem to be more popular with them than with men. While there are nearly three times as many women students in the regular schools as there are in the homœopathic, the ratio to male students is much smaller. In the regular schools the number of women is 902, which is only 5.1 per cent. of the whole number; but in the homœopathic schools there are 351, or 21.1 per cent. of the whole number; while in the eclectic schools there are 86, or 10.7 per cent. In all the medical schools there are 1,419 women, or 6.5 per cent. of the whole number.

Medical students at the present time are required to have a better preliminary training; they are required to spend a longer time in the study of their profession, and must undergo severer final examinations than students in the other professions—law, theology, dentistry, and pharmacy. If the interests involved are considered, it would seem to be only proper that the education of physicians should rank especially high. In the study of medicine the previous instruction of even a well-educated person gives him but little knowledge of those things which he must learn before beginning the practice of medicine. His previous training will simply enable him to grasp more quickly and fully the new ideas presented, and accelerate his progress along paths hitherto un-

trodden. It is therefore absolutely necessary, not that he should be capable of properly receiving instruction, but that he should also devote much time to receiving it, and be able to give clear evidence of his medical knowledge before receiving a license.

**The Construction of a Tesla-Thomson High-Frequency Coil.**—The following description, by Professor A. F. McKissick, of a coil large enough to give a five-inch spark and excite Röntgen rays is from the August number of the *American Electrician*, to the editor of which we are indebted for the cuts.

To excite the Tesla-Thomson coil, a high-potential transformer of from 10,000 to 15,000 is necessary. The construction of this transformer will be first given. Fig. 1 gives a partial cross-section of the transformer,

FIG. 1.—High tension transformer.

which is made as follows: A two-inch iron pipe, sixteen inches long is slotted the whole length, either in a milling machine, planer, or shaper. This slot need not be more than a sixteenth of an inch in width. The pipe is then insulated with ordinary wrapping paper to an outside diameter of two inches and an eighth, shellac being

FIG. 2.—Form for winding coils.

freely used, and is then wound with No. 13 B. & S. double cotton-covered wire for its whole length (one layer). It is then covered with paper and shellacked until the outside diameter is two inches and five eighths.

The next step is to fill the pipe with soft iron wires, No. 16 B. & S., each wire being cut eighteen inches long. This completes the primary winding of the high-tension transformer.

The secondary winding of this transformer consists of ten coils wound in a form and thoroughly taped and insulated. This form is shown in Fig. 2, and can be easily made of wood. The wire is wound in this form, shellacked, removed, taped, and baked. These coils are then slipped over the primary winding, between each coil being placed a disk of cardboard an eighth of an

in thick, care being taken to connect the coils so that none will be in opposition.

The spark gap (see Fig. 3) is made as shown in diagram. The copper wires fit rather close in the holes drilled through the hard-rubber tubing, so that the length of gap can be adjusted with ease.

The condenser is made of ordinary ten-by-twelve-inch window glass. A sheet of tin foil eight by ten inches is pasted on one side of the glass with shellac, leaving a margin of one inch (see Fig. 4). A strip of tin foil two inches wide is placed across one corner, this strip being placed alternately on each side. For each side of this condenser there should be fifteen plates.

To build this condenser proceed as follows: Place on a smooth surface a condenser plate with the connecting strip projecting on the right. On top of this plate place another piece of glass, ten by twelve inches, that has no tin foil on it at all. Then place a condenser plate with the strip projecting on the left. Then a piece of glass without tin foil, and on top of this a condenser plate with the strip projecting on the right, and so on. This construction gives two thicknesses of glass between each sheet of tin foil, which is absolutely necessary.

The high-frequency coil is made as follows: Wind

FIG. 3.—Spark gap.

an eight-inch paper cylinder eighteen inches long with No. 31 B. & S. double cotton-covered wire (or larger), leaving a margin at each end of about one inch. This is

FIG. 4.—Condenser plate.

the secondary winding. The primary winding is placed on a twelve-inch paper cylinder eighteen inches long and consists of fourteen turns of four No. 8 B. & S.

double cotton-covered wires in parallel. Each of these No. 8 wires is wound on separately, then the four ends at the beginning and ending are soldered together. Between wires of different polarity, as an extra precaution,

FIG. 5.—Primary and secondary coils of high-frequency transformer.

two turns of cord are wound. The primary and secondary coils are then shellacked and baked. After being baked, the secondary coil is placed concentrically (see Fig. 5) inside the primary and the connections as shown in Fig. 6 then made.

The primary of the high-tension transformer must be excited with an alternating current. With a frequency of 60 cycles a second 50 volts will suffice, and for 125 cycles per second 100 volts. The length of the spark from the secondary of the high-frequency coil will depend on the width of the "spark gap"; consequently, in exciting a tube it is best to start with the "spark gap" very short, then gradually increase until the tube is properly excited. When the terminals of the secondary high-fre-

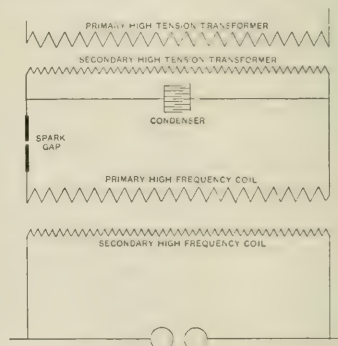

FIG. 6.—Diagram of connections.

quency coil are separated farther than five inches, a spark will pass from the secondary to the primary of the high-frequency coil. By the use of a good insulating oil a much longer spark can be obtained from the high-frequency coil, but for exciting Röntgen-ray tubes a five-inch spark will be sufficient.

Lectures and Addresses.

LECTURES ON ANGINA PECTORIS  
AND ALLIED STATES.\*

By WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE IV.

I. SYNCOPE ANGINOSA. II. THE ADAMS-STOKES SYNDROME.  
III. ANGINA SINE DOLORE. IV. CARDIAC ASTHMA.

I wish to call your attention in this lecture to several interesting conditions closely allied to true angina which may either develop in the course of an attack or which occur spontaneously in the subjects of heart disease or arterio-sclerosis.

I. You remember that Parry called angina *syncope anginosa*, and this feature of *faintness* may detain us for a few moments. The distinguished old Bath physician, from whose monograph I have so often quoted, says: "The angina pectoris is a mere case of syncope or fainting, differing from the common syncope only in being preceded by an unusual degree of pain in the region of the heart." This is too strong a statement, as in a majority of the paroxysms, though the pallor and other vasomotor phenomena of a *faint* may be present, consciousness, unhappily for the poor victim, is not lost. In looking over the histories of my cases I do not find *fainting*, as we usually understand the term, to have been a common symptom. There is, of course, the syncope of a fatal paroxysm—*S. letalis*, as Quain terms it. During a severe attack the patient may lose consciousness—in Case XXVI Mr. S. was once picked up on the street. In Case XXV, mentioned in connection with angina and epilepsy, we could not determine the nature of the attacks of loss of consciousness. Another feature of which I have no illustrative example is thus referred to by Broadbent:† A patient who has ceased to suffer with attacks of angina "may have attacks of what he calls faintness, in one of which he ultimately dies. These which have lost the title to the name angina have an equally serious significance." And, lastly, an individual subject all his life to fainting spells may present remarkable attacks of the nature of Gairdner's angina pectoris *sine dolore*, about which I shall speak shortly.

CASE XXXIV.—T. J. J., aged sixty-one years, seen with Dr. King, May 11, 1895, complaining of curious attacks which occur on the street while walking.

The patient has been a very vigorous, healthy man, has never had syphilis, and has been abstemious. He has had two attacks of sciatica in the past ten years, the last, a severe one, two years ago; he has had no joint affections. He has had an exceptionally healthy life. From boyhood, however, he has been liable to faint on very trifling provocation, such as a vomiting attack, a

slight shock, the sight of blood, or the extraction of a tooth. From any of these causes he would drop instantly in a faint. He has not had a spell of this kind for more than two years. His present attacks date from eighteen months ago. The first one occurred when walking from the Union Station to North Avenue. He had a tingling feeling in the hands, and then a sudden fainting sensation, as though he was going to die. *He had no pain.* The attack passed off in a few moments. He took the street car and then walked to his home, having a second attack on the way. Subsequently he had these attacks at intervals, always when walking on the street.

On November 22, 1894, he had two very severe attacks, and he then consulted Dr. King. In every instance they have come on while he is walking. He does not think that going up hill or walking against the wind makes any difference. He has never had an attack at his place of business or in his home, and he is able to go up three or four flights of stairs quickly and readily without the slightest embarrassment. They come on with abruptness, begin now every time with a feeling of numbness and tingling in fingers and hands, which sometimes extends up the arms, and which is not more on one side than the other. He has never vomited in an attack; there is no cough, and there is no dyspnea. He turns of an ashen-gray color, sweats profusely, and feels in each one as though he would sink away and die. It is this sensation of impending dissolution which has alarmed him so much. He has never had the slightest sensation of pain. During an attack he is not immobile, but he has to move slowly. The day before yesterday, for example, he had an attack before he reached his house, and was able to get up the steps into the porch and close the door; but he had then to sit down, and he was found there by his son in a condition of exhaustion and sweating profusely.

He was a healthy-looking man, with iron-gray hair and mustache; no arcus; the pupils were normal. He was not stout, but well nourished. The pulse was 72 and regular, the vessel wall not specially sclerotic, and the pulse could be compressed readily.

There was a slight throbbing in the vessels of the neck. The venules were marked along the course of the diaphragm. On auscultation there was a short, sharp, somewhat rough murmur heard only in the apex region and as far as the mid axilla. The apex beat was not visible, but was palpable in the normal situation, in the fifth space just below the nipple. The heart impulse was felt also below the ensiform cartilage; there was no thrill. The dullness began on the fourth costal cartilage and did not extend beyond the nipple line. The percussion on the manubrium was clear. The aortic second sound was not accentuated. Both sounds were clear in the vessels of the neck; the second was a little loud at the sternal notch.

The lungs were clear. Posture made no difference in the heart sounds or in the apex murmur.

The liver was not enlarged; spleen not enlarged.

After dressing, and in the erect posture, the pulse was 88 a minute.

June 14, 1895.—I heard of this patient to-day. He has had no attacks for a month.

May 29, 1896.—The patient was seen to-day. He had a severe attack in April of this year, one of the worst he has ever had. After a hearty dinner he was attacked in the street. There was no shortness of breath, but an "all-gone" feeling, as though he were going to expire,

\* Delivered to the Post-graduate class, Johns Hopkins Hospital.

† *British Medical Journal*, 1891, i, 747.

but there was no pain with it; sweat "rolled off" him. He was well that evening. He has had in the year about eight mild attacks. He had an attack yesterday. They occur nearly always after meals.

II. *The Adams-Stokes Syndrome*.—There is a most interesting group of symptoms associated with myocardial changes, and sometimes with angina, to which Robert Adams, of Dublin, first called attention, and which Stokes subsequently described more fully. Most of the text-books refer to a pseudo-apoplexy in connection with fatty or fibrous myocarditis, a condition in which with a permanently slow pulse the patient has transient vertigo, or falls into a deep coma, with or without convulsive movements. Huchard has given it the name *maladie d'Adams* or *Stokes-Adams*. As it is always pleasant and profitable to have the author's first-hand description of any symptom or disease, I will give you an abstract of the case recorded in the *Dublin Hospital Reports*, vol. iv. Adams, I may remind you, was one of that distinguished band of men, including Cheyne, Colles, R. W. Smith, Graves, Stokes, and Corrigan, who gave such renown to the Dublin school in the first half of this century. He is best known through his superb work on rheumatoid arthritis. Adams's patient was a man, aged sixty-eight years, who had had in seven years not less than twenty apoplectic attacks, each of which was preceded for a few days by hebetude and loss of memory. The pulse was permanently slow, and at the time of the attacks became slower. There was never any paralysis. Death followed an attack. Post mortem, the heart was found to be excessively fatty. There was no note about the coronary arteries. R. W. Smith\* also noted the condition of very slow pulse with fatty heart, and Stokes described it more fully,† and suggested the name false or pseudo-apoplexy. He laid stress on the syncopal character of the attacks, their frequency, the absence of paralysis, and the good effect of a stimulant rather than a depleting plan of treatment. The first case which he gives is very remarkable, and is worthy of a brief abstract, as recent Anglo-American authors have not dwelt specially upon this symptom-group: A man, aged sixty eight years, was suddenly seized with a fainting fit, which recurred several times in the day. For the three years before he was admitted to the Meath Hospital he had never been free from the attacks for any length of time, and had had at least fifty such seizures. A sudden exertion or a distended stomach was most apt to cause an attack. He had no convulsions, nor was there ever anything like paralysis. He was perfectly insensible for four or five minutes. The pulse was 28 per minute, and the arteries were "in a state of permanent distention, the temporal arteries ramifying under the scalp, just as they are seen in a well-injected subject." There was a soft *bruit* with the first sound. The threatenings of attacks

he could recognize, and he had often warded off a seizure by turning on his hands and knees and keeping the head low.

In passing I may remark that you will find in this paper Stokes's original description of the Cheyne-Stokes breathing, which, though fuller, is not a whit better than Cheyne's account published thirty years before.

Permanent slowness of the heart action and vertigo or syncope are the two distinguishing features of this syndrome. Do not forget that slowness of heart's action is the special feature, not simply a diminished number of pulse beats at the wrist. In myocarditis, in mitral-valve disease, and as an effect of digitalis the radial pulse may appear very slow—35 to 40 per minute—while the heart beats are exactly double. In the bigeminal type of heart beat the second pulse wave very often does not reach the wrist, and may lead a novice into the serious error of supposing that there is an extreme bradycardia. In "Adams's disease" the pulse rate may fall to 30 or 20 per minute, or, in extreme cases, even to 10 or 5.

The patients are usually advanced in years, and show often an extreme grade of arterio-sclerosis, the arteries feeling, as Stokes remarked, both full and hard.

The cerebral symptoms are those to which naturally chief attention has been paid. Vertigo is the most common, and is usually transient and oft repeated. Actual syncope of three or four minutes' duration, resembling closely the *syncope anginosa*, and doubtless of the same nature, has been the special feature in some cases; while in others the attack has been apoplectoid in its character, of longer duration, and has been complicated by convulsions. Huchard regards the slow pulse as a result of changes in the vagi centres, due to disease of the arteries of the medulla. He calls this form of arteriosclerosis the *cardio-bulbar*. Transient disturbances in the cerebral circulation, so common in the subjects of advanced arteriosclerosis, are responsible for the syncope and the apoplectoid attacks, which remind one of the temporary hemiplegias or monoplegias, the aphasias, and the transient paraplegias, to which these patients are subject.

Typical cases are not common. The most remarkable instance recorded in this country is by Prentiss,\* of Washington. A man, aged fifty-three years, with advanced arterio-sclerosis, had for two years a pulse range of from 11 to 40 per minute. During this time he was subject to innumerable fainting spells, and had sensations of tightness across his chest. Before his death—which took place suddenly—he was delirious for several days. The heart was enlarged, but neither the aorta nor the coronary arteries were atheromatous. The sections of the medulla showed congestion of the vessels, but no apparent lesions. Dr. Prentiss presented this remarkable case at our meetings, and I remember very distinctly the advanced sclerosis of the arteries.

The following case belongs to this Adams-Stokes

\* *Dublin Journal*, ix.

† Observations on some Cases of Permanently Slow Pulse. *Dublin Quarterly Journal*, 1846, p. 73.

\* *Transactions of The Association of American Physicians*, vols. iv, v, and vi.

type, but the patient has, in addition to the vertigo and slow pulse, a sense of severe oppression in the chest, suggestive at least of an oncoming angina:

J. W., aged forty-six years, seen with Dr. Houston, of Troy, N. Y., February 13, 1895. The family history is good. With the exception of typhoid fever twenty years ago, he has always been well and strong. He has never had rheumatism, chorea, or syphilis; he has never worked very hard with his muscles. He is temperate.

His present symptoms began about two years ago with uneasy sensations in the chest on walking fast. At first not at all severe, within the past six months they have become very distressing. He has not been able to lie flat on his back, but can lie comfortably on either side with the head a little raised. He has no sharp pain in the chest, but uneasy sensations and a feeling of suffocation. He never has any cramplike or agonizing feeling; he has had at intervals severe vertigo, but has never lost consciousness. The unpleasant sensations in the chest are particularly apt to be present in the morning. He has had no dyspepsia, but of late has become very nervous about himself. He has to walk slowly, and on going up the slightest incline he feels the sense of oppression in the chest. He has no cough, no palpitation. About a year ago it was noticed that his pulse was very slow, and in the early morning it has on several occasions been counted as low as 20 per minute.

The patient was a healthy-looking man, with iron-gray hair; there was no arcus; the pulse was 34 to the minute; the tension was plus, the upstroke a little labored, and the pulse wave was well sustained. The chest was large; the cardiac impulse was not visible; there were no areas of abnormal pulsation; the aorta was not palpable in the sternal notch; there was no increase in the area of dullness; no apparent hypertrophy; no shock at the base; no thrill.

On auscultation, the sounds in the apex region were clear; over the body of the heart there was a roughish, systolic bruit, heard also at the aortic cartilage, transmitted feebly to the vessels of the neck. The second aortic was heard, but was not specially accentuated; there was no accentuation of the pulmonary second. There was no enlargement of the liver or spleen.

I heard from this patient in April, 1896. He has been a great deal better. He still has the brachycardia, but the vertigo is not so troublesome.

III. *Angina Pectoris sine Dolore*.—The three elements in an attack—the pain, the sense of anguish, and the abrupt ending of life—may be dissociated. There may be only the severe pain, there may be a sense of *angor* and oppression without any pain—*angina sine dolore*—or death may occur without a moment's warning.

The recognition of a group of cases in which the element of *pain* is subsidiary was made by Professor Gairdner. His brief description is as follows:

"Apart from what has been variously termed cardiac asthma, dyspnoea, or orthopnoea, which in many cases receives its clear explanation from the associated states either of the pulmonary circulation or of the lungs, bronchi, and pleuræ, as disclosed by physical signs, there is often an element of subjective abnormal sensation present in cardiac diseases which, when it is not localized through the coincidence of pain, is a specially indefinable

and indescribable sensation, almost always felt to be such by the patient himself. I make this remark deliberately, as the result of experience, and well knowing that it is liable to be brought into question in particular instances; that, in fact, a large part of what has been described under the titles given at the commencement of this paragraph has been inextricably confounded by systematic writers with the sensation, or group of sensations, to which I refer. To this group of sensations, when not distinctly accompanied by local pain, I have, in various instances, given the name of *angina sine dolore*, recognizing thereby what I believe to be its true diagnostic and pathological significance, and its alliance with the painful angina of Heberden; the pain in which, however, as we have already seen, is an exceedingly variable element, both in degree and in kind."\*

Let me read you the histories of several cases of this variety:

CASE XIII.—Mr. H., merchant, aged fifty years, who had suffered repeatedly from attacks of gout, consulted me on October 21, 1892, complaining of oppression and pain in the chest, and bronchitis. Throughout the summer he had had at times very severe pain in the region of the heart and down the left arm. When first seen he was anæmic, with a dilated heart and an enlarged liver. With rest and iron he did very well. I saw him at intervals through the winter; the attacks of pain ceased, but he had severe cardiac asthma at night, which troubled him very much. I subsequently saw him in several attacks which followed the exertion of walking from the street car to my house, in which the feature of dyspnoea was subsidiary, and that of great oppression in the chest the most important. In these attacks the color changed, he became pale, looked very distressed and haggard, remained motionless, the forehead covered with sweat, the hands cold, the pulse feeble and irregular. After the attack he expressed himself as having had a feeling of indefinite distress without actual pain. There was no dyspnoea. The attacks at night were sometimes very severe, and he dreaded to go to sleep lest he should be roused in one. Though in the summer of 1892 he had had repeated attacks of what seemed to be true angina, yet he subsequently had only attacks of the kind just described.

In the spring of 1893 he became much worse; there were signs of dilatation of the heart, with the gallop rhythm, and a soft apex systolic murmur. He had cardiac dyspnoea, as well as attacks of severe oppression, and in one of these he turned on his side and died suddenly.

An attack of an *angina sine dolore* may be the very first indication of cardiac trouble.

An intimate friend, a man of about fifty-six years of age (Case V), of excellent habits and great energy, while on a visit to England, walking one Sunday afternoon with the late Dr. Hack Tuke up a slight acclivity, felt, as he expressed it, a sense of intolerable distress about the heart, turned pale, vomited, and for a few minutes could not move from the place at which he was attacked. He recognized the serious character of the paroxysm, and said that had there been the severe pain he would have

\* Reynolds's *System of Medicine*, art., *Angina Pectoris*.

called it angina. The attack was the starting point of a series of very distressing seizures, culminating in a protracted condition of cardiac dilatation, which kept him in his bed in Paris for several months. On his return he was wonderfully better, took up his work, but soon had another breakdown, beginning with attacks of *angina sine dolore*. In one of these which I saw the pallor was extreme, the extremities were cold, a clammy perspiration bathed the forehead and face, the pulse was extremely feeble, and I thought any moment that he would die. After a protracted attack of cardiac dilatation, persistently feeble, irregular pulse, without any dropsy, but with the most remarkable psychical manifestations, he recovered, and was able for more than three years to attend to his duties. Then he had a sudden, more rapid breakdown, with cardiac dilatation, and he died between three and four years from the date of his first attack. I have already shown you sections from the coronary arteries in his case, which were sclerotic, and the myocardium was fibroid in places.

CASE XXX.—E. H., aged fifty-four years, seen July 11, 1895, complaining of attacks of oppression in the chest, to which he had been subject for five years.

The patient was a remarkably healthy looking man, of good color, of medium size, with iron-gray hair. Thirty years ago he had syphilis, but was thoroughly treated at Kreuznach, and he has had no troublesome symptoms. He married eight or ten years ago, and has healthy children. He has been a very heavy smoker from his eighteenth year; otherwise temperate; he has never done heavy work.

Five years ago he noticed that when making any extra exertion he had a sensation in the chest which compelled him to stop. After resting for a moment or two he could then go on. There was no pain with it. He was smoking excessively at the time, and after stopping the tobacco the attacks became less frequent; but for two years they troubled him a good deal.

Three years ago he retired from business and spent a year in Europe. While there he had his first severe attack. While going home after a hearty dinner with a friend, he was seized with a sensation in the chest, had to stop in the street, and was taken to his hotel. The feeling in the chest was as if everything in it was being drawn together and tightened, but without any sharp pain. He was very pale, he perspired, and the attack lasted until the night. After the attack he had great depression of spirits.

The only other severe attack he has ever had was six weeks ago. He had been feeling very well, but before sitting down to dinner an annoying circumstance developed, and while still under the influence of the irritation he sat down and ate heartily. Immediately after dinner he had an attack of terrible oppression in the chest, feeling, as he expressed it, as though the life was being squeezed out of him. The slightest movement would increase the oppression. In the attack absolute quiet is what he desires. He does not even wish to be spoken to, but feels that the mind must be at rest. The immobility is evidently a very characteristic feature. When the sense of constriction and drawing is upon him, he says he could not force himself to budge an inch. In these severe attacks the pulse becomes very slow. The sensation is in the breastbone in the middle.

In describing his sensations during a conversation at least three quarters of an hour he did not use the word pain once, and states expressly that it isn't anything like pain, but an indescribable sensation of con-

striction and oppression. As he says, "he feels as if the end of everything had come"; at the same time "he feels so healthy that behind it, as it were, there is a feeling that he still has a long time to live."

In the two severe attacks a feeling extended into the muscles of the arms, not into the skin, he says, but there was a sense of strain and soreness in them.

The small attacks, as he calls them, recur with great frequency, and almost any day he has what he calls a *hindrance*; and if he makes any exertion of more than usual effort he has to stop short and wait a few moments until the sensation passes away. This may recur two or three times, and then, if he takes it slowly, he can subsequently walk two or three miles without any distress.

Two other circumstances which will bring on an attack are an unusually full meal and any mental worry. He never has the attacks at night.

The pulse was 72 when he was at rest; after his running upstairs and down, 104: the tension was not increased; the superficial vessels were not sclerosed.

The apex beat was only just visible in fifth within the nipple line. The shock of the first sound was felt, not of the second. Area of superficial dullness was reduced by emphysema. Both sounds of the heart were clear; first a little flapping and valvular; no accentuation of aortic second sound. The examination of the heart was entirely negative. The liver was not enlarged.

July 12th.—The patient stayed in town until I could see his condition in an attack. He had had two to-day, one quite light in the morning. He walked into the room somewhat deliberately, talked clearly and well, and had not changed in color. He said he had a sense of great distress just beneath the breastbone. The pulse was small and hard, 103 a minute, with distinctly increased tension. After sitting down for a few moments his skin became moist, but he did not become pale. In the course of a few minutes the attack passed off with a feeling of glow. Afterward there was a very decided change noticeable in his pulse, which was softer and fuller, and of decidedly lower tension.

He was advised to stop smoking, and ordered a course of nitroglycerin. I heard from him in September and of him in May (1896). He still has the "smaller attacks," as he calls them.

The attacks may alternate with those in which agonizing pain is present, or they may entirely supplant the severer type. Some of the milder paroxysms, indicating the beginning, as it were, of the trouble, appear to be of this kind.

An iron-gray, healthy-looking man, aged sixty-four years, of good habits and excellent history, consulted me, May 25, 1895, about curious sensations in the chest. In October he noticed that when walking fast there was a peculiar sensation about the heart, as he said, "an aureole, which spread up his neck and head and went out to the hands." If he stopped for a moment, the sensation would "recede like a glow"; if he went on, it would culminate in a pain which would compel him to stop. There was no sense of faintness, no dyspnoea, and he did not sweat. They have always followed exertion, and he has had as many as four or five attacks in a day. His arteries were a little stiff, but the aortic second sound was not accentuated. The top of the pinna of the left ear was calcified. He had never had gout. I heard from this patient on February 6th of this year. The attacks

continue, though less frequent—only two or three a week. They are characterized by the same spreading glow, beginning at the heart, and lately the curious sensation has passed down the right arm alone.

IV. *Cardiac Asthma*.—Heberden insisted that in the paroxysm of true angina there was *no shortness of breath*, and yet we find a few years after his description the term *asthma* applied to the condition: *Asthma dolorificum* (Darwin), *A. arthriticum* (Schmidt), *A. convulsivum* (Elsner).

In reading the reports of the cases published within the first half century after Heberden's paper, it is very evident that much confusion existed, and nearly all forms of cardiac distress were termed angina. Desportes emphasized this on the title-page of his monograph (1811) on angina, which he said was a malady "presque toujours confondue avec asthma." The earliest and the latest, as it is the most urgent, symptom in heart disease is *dyspnœa*, which the older writers characterized as *asthma*; and as it forms a common feature in cases of angina pectoris it is not surprising that more or less confusion prevailed. Even Stokes does not seem to have had a very clear conception of the distinctions between these states, since he says that the disease which "most often gets the name of angina pectoris might be more properly designated as cardiac asthma."

What, then, is this condition? Go into the wards and ask the patients with valvular disease of the heart as to the very *first* symptom of their trouble. With scarcely an exception they will answer, "Shortness of breath." Take a long series of histories of cases of arterio-sclerosis; you meet with the same complaint at the very outset. To the burly, obese draymen, to the heavy workers and the hard drinkers, and particularly if in addition they have been victims of the pox, Nemesis pays her first visit in an attack of shortness of breath—the *first indication of broken compensation* in an enlarged heart.

Clinically, we meet with various grades of intensity in this cardiac asthma. An exertion, the ascent of a pair of stairs, which may call forth only a fraction of the reserve force of a normal heart, may be too much for a right ventricle (in a case of mitral stenosis), or for a left ventricle (in a case of aortic insufficiency), and at the head of the stairs the patient pants, and is perhaps a little cyanosed. In chronic valvular disease such symptoms may recur on extra exertion for years without much significance; when the cardiac dyspnœa develops spontaneously, *without extra exertion*, the breakdown is not far off; and in the slow, too often watery progress to the grave no other symptom is so distressing to the patient. In cases of advanced arteriosclerosis there are often attacks of dyspnœa of great intensity recurring in paroxysms, often nocturnal. The patient goes to bed feeling quite well, and in the early morning hours wakes in an attack which, in its abruptness of onset and general features, resembles asthma. There is usually a sensation of precordial distress, a feeling of constriction and op-

pression, what the Germans call *Beklemmung*. Two other features about this form of attack will attract your attention—the evident effort in the breathing and the presence of a wheezing in the bronchial tubes and of moist râles at the bases of the lungs. The patient may spring from the bed and throw open the window in his terrible *air-hunger*, and he assumes an attitude most favorable to the working of all the accessory muscles of respiration. Slight cyanosis is usually present, and in severe paroxysms a cold sweat breaks out in the face and limbs. The pulse is feeble, often irregular, and very small, and on auscultation one hears either gallop rhythm or the fetal type of heart beat. Death may occur in the attack, as in Dreschfeld's case, the history of which I gave you in Lecture III. This form of cardiac asthma occurs with great frequency in some of the subjects of angina pectoris, as in Cases V and XII.

And, lastly, the type of breathing known as *Cheyne-Stokes* is sometimes a form of cardiac asthma, and it is not uncommon in angina pectoris. The curious pause in his respiration of which John Hunter spoke was probably a period of apnoea in a paroxysm of Cheyne-Stokes breathing. It was first described by Cheyne in a case of fatty heart, and you will find it more frequently associated with chronic myocarditis than with any other form of heart disease.

The following case presents features of Gairdner's *angina sine dolore*, with characteristic cardiac asthma:

Mr. X., aged sixty-seven, seen March 9, 1895, with Dr. Claribel Cone, complaining of attacks of terrible oppression in the chest and a sense of impending death.

The patient was a very large-framed, well-nourished, vigorous-looking man. He had been always a very active business man, temperate, but a heavy smoker; he began in his eighteenth year, and has used as many as eight cigars a day.

For several years he has occasionally been roused from his sleep with a feeling of oppression in the chest, but it has never been very severe. For the past two or three weeks he has been very short of breath, and has had paroxysms of great oppression in the chest, with dyspnœa, feebleness of the circulation, cold, clammy sweat, and a sense of impending dissolution. During these attacks there is no actual pain. Mental excitement or muscular exertion will bring on the oppression and dyspnœa. He came to-day, however, in the street car, and walked half a block without much difficulty. During the examination he had well-marked Cheyne-Stokes respiration.

The pulse was 104, of moderate tension, easily obliterated; the vessel wall was a little stiff. The apex beat was feeble, just at the mamillary line; there was no shock of either sound to be felt; there was gallop rhythm at the apex, but no murmur. The second aortic sound was a little accentuated. The liver was not enlarged.

At 11 p. m. on the 9th the patient had a very severe attack of terrible oppression in the breath, with drenching cold sweat which soaked the clothing. During the attack the pulse was 104 and regular. The Cheyne-Stokes breathing became aggravated during the attack.

In this patient the attacks were more than ordinary

cardiac dyspnoea. In addition to a sensation of awful oppression in the chest, there was a sense of impending death, and the cold, clammy skin showed profound involvement of the vasomotor system.

For several weeks this patient seemed very ill. There were two interesting points in his treatment. The digitalis seemed to have helped him very much when the pulse tension was low; subsequently he got a great deal of relief from the full doses of nitroglycerin. Through the winter of 1895-'96 he remained pretty well, though subject to occasional attacks.

I can not leave this question of cardiac dyspnoea, of equal importance pathologically and clinically, without referring briefly to certain recent works upon it. A. Fraenkel, in the third edition of the *Real-Encyclopädie*, under Asthma, has a full and clear statement of the condition. Rosenbach's *Herzkrankheiten* has the most exhaustive discussion on the whole subject, full of suggestive ideas, but not easy reading, apparently not even to his countrymen, as Professor Martius speaks of the *Lehrbuch* as "in einer etwas dunklen Sprache geschriebene." The essence of Rosenbach's views on the relations of cardiac asthma and angina may be gathered from the following sentence (page 377): "Dass nur eine Veränderung in der Art der Muskelcontraction, die die Stärke der Muskelleistung durchaus nicht zu beeinflussen braucht, wohl aber beeinflussen kann, Impulse für die sensiblen Bahnen liefert, die je nach der Erregbarkeit derselben und der Beschaffenheit der betroffenen Bahnen, die verschiedenen Formen von Schmerz und Angst auslösen, die wir als Stenocardie bezeichnen, während die Veränderung im Muskel die zur Leistungsschwäche führen, das Hauptsymptom des Asthma cardiacum, den wahren Lufthunger hervorruft." Or, as he says in another place, "die wahre Stenocardie ist ein blosses Zeichen der Regulationsstörung, das Asthma cardiacum ein Zeichen der Compensationsstörung."

Von Basch and his pupils\* have endeavored to show that whenever, either from spasm or weakness of the left ventricle, the blood pressure in the auricle is raised, cardiac dyspnoea follows in association with two important changes in the lungs, viz., swelling and diminished elasticity = *Lungenschwellung* und *Lungenstarrheit*. The swelling, which may even be determined by percussion, results directly from the overdilatation of the capillary network in the air cells, and to the same cause von Basch attributes the lessened elasticity. The ratio between the respiratory work and the intake of air is reduced; and, as Zerner remarks (*Studien*, Bd. iii), the peculiarity of cardiac dyspnoea is in this respiratory insufficiency, not in the rapidity and depth of the breathing. The "excursionsfähigkeit" of the lungs is lessened, and the amount of air inspired is not proportionate to the work done. Fraenkel also refers to the influence of the venous engorgement of the mucous membrane of the finer bron-

chioles as limiting the freedom of ingress and egress of the air to the alveoli.

When we recall to mind the features of the attack in cardiac asthma and in certain anginal seizures, the similarity of the condition, as Huchard remarks, to an acute emphysema, the views of von Basch appear to possess at least a reasonable probability.

## Original Communications.

### THE CONTROL OF HÆMORRHAGE IN SOME OPERATIONS IN THE NOSE AND THROAT.\*

By A. COOLIDGE, JR., M. D.,

BOSTON.

IN many operations under an anæsthetic in the upper respiratory tract an important problem is first to prevent any possible hæmorrhage from threatening respiration, and, secondly, to be prepared to control the hæmorrhage locally. The question of the best position in which to place the patient for operation is an important one and depends largely upon the former. Except for this danger of blood in the pharynx, the most generally convenient position in which to operate is with the patient horizontal on a table. Less assistance is required than with a patient in a sitting posture, the light is generally better, and the patient is more easily handled in an emergency. On the other hand, if blood enters the pharynx, the direction of gravity hinders instead of help-

Fibrosarcoma.

ing us in keeping respiration clear, and this position is consequently impractical if the seat of operation is behind the posterior nares. But I wish to make a plea for its more frequent use when the source of bleeding is confined to the nasal cavities or accessory sinuses. This is made possible by the simple expedient of plugging the posterior nares from behind, which effectually stops all danger of blood finding its way into the pharynx. For instance, for the removal of a nasal new growth, or the

\* *Klinische und experimentelle Studien*, i, ii, and iii, particularly Bd. iii, 1896.

\* Read before the American Laryngological Association at its eighteenth annual congress.

correction of an extensive deviation of the septum, when the patient is anesthetized he is placed horizontally on the table, the cord for the posterior plug passed through the unobstructed nostril, a piece of gauze or sponge sufficiently large to close both posterior nasal openings attached, passed into the nasopharynx, and pulled firmly forward. This is removed when bleeding has stopped, before the patient recovers consciousness, and produces no disagreeable results.

Myxoma.

A modification of the horizontal position, what is commonly known as the Rose position, with the head bent sharply back over the edge of the table, keeps the blood away from the larynx by gravity. It fills the nasal cavities and comes out of the mouth, or flows over the hard palate and upper lip, and leaves the lower pharynx and larynx clear. I find this position recommended not only for operations in the nose and face, but also for cleft palate, adenoid vegetations, new growths of the pharynx, and for opening retropharyngeal abscess. There is no doubt that the blood all flows away from the larynx if the head hangs directly downward, but I think that to most operators this position is not entirely satisfactory. It is difficult to control the patient in case he moves or vomits, and the seat of operation at first seems upside down and hard to reach. Familiarity with the position undoubtedly lessens these disadvantages, but it seems to me that for the removal of adenoid vegetations, for instance, the amount of hæmorrhage is materially increased by the dependent position of the head. The nasopharynx fills up with blood and fragments of adenoid tissue, making it difficult to feel satisfactorily with the forefinger. This position is especially to be recommended for operations of the palate. A good light is obtained, and the parts are easily reached.

Another modification of the horizontal position is that of Trendelenburg, where the foot of the table is raised and the patient hung up, as it were, by the knees. Here the direction of gravity protects the trachea and bronchi as well as the pharynx. This is distinctly the position for thyrotomy, or for an operation deep in the pharynx, perhaps even for tracheotomy.

There remains the sitting posture, in which the patient is held in a chair opposite the operator. We are so accustomed to this position with patients who are not under an anæsthetic that it is natural that we should be influenced in its favor. If the head and upper part of the body are inclined well forward, the drainage of the nasopharynx is into the nose and not into the pharynx unless the nose is stopped. Most of the blood from the tonsils will come forward into the mouth. The pharynx is generally kept more or less clear, and the larynx protected by frequent swallowing, especially if the patient is not too profoundly under ether or chloroform; and it can be swabbed out if necessary. But the operator must bear constantly in mind that the only safe direction for the drainage, after blood has passed below the fauces, is into the stomach. In case the heart becomes weak this position is a bad one, and it may be necessary to lay the patient horizontal at any time. It is absolutely necessary for safety that sufficient assistance should be on hand to easily and quickly control the patient; to tip the head and body well forward in case of bleeding or vomiting; to keep the gag in place; to hand instruments or sponges, and if a special operating chair is not used, to transfer the patient to a table in case of collapse. This position is therefore much easier in the case of children than with adults, but with sufficient assistance it is the most universally applicable one for operations in the nasopharynx and mouth.

Angioma.

For the local control of hæmorrhage of any importance, if the bleeding vessel can not be seized, the first thing that we should think of is compression, if possible.

Any part of the nasal cavity can generally be reached anteriorly with suitable instruments, and strips of gauze carried to and packed firmly against the bleeding part. If a new growth, or an extensive deviation of the septum prevents this, and the obstruction can not readily be removed, it may be necessary to close the posterior nares from behind. It seems to me that attempts to control bleeding here or in the nasopharynx by styptics or astringents is generally a mistake. A constant outflow of blood washes away whatever is put on, from the only spot where it is needed, and irritates other parts, or fills the cavity with dirty coagula. Clean gauze left in place is more certain at the time and gives a feeling of security against secondary bleeding.

The probability of hæmorrhage as well as of pain must influence an operator in deciding whether an anæsthetic is necessary or not. If the patient is likely to be unruly it is often better to use ether or chloroform when otherwise it would not be done.

Fibroma.

The amount of bleeding which we may expect from the cutting through of an attachment of a new growth depends not so much upon the size and number of the vessels supplying the growth as upon the nature of the tissue surrounding them, and the consequent possibility of retraction of the individual vessels.

In order to show this more clearly, I have here sections of different new growths or hypertrophied glands. Each section is cut parallel to and as close as possible to the surface made by the instrument used for its removal, and, consequently, cuts directly across the blood-vessels entering the tumor. In the tonsil and adenoid vegetations the vessels are numerous, none of them large, and they enter free, parallel to the fibres of the interstitial tissue between the lobes of the parenchyma. They would therefore retract readily. In the pedicle of the myxoma there are a few large vessels, but here the structure of the neoplasm surrounding the vessels is so very soft that nothing hinders their speedy retraction. The fibroma and fibrosarcoma were clinically very similar. Both occurred in boys of seventeen. The tumors were both attached to the basilar process only, and filled

one lower meatus and the nasopharynx. They were both removed with the cold wire by the method which I will later describe. The pure fibroma bled freely and persistently; the fibrosarcoma did not. In the section

Faucial tonsil.

of the former we see a very large number of vessels, and, although not large, they have thick walls and are surrounded by dense fibrous tissue which might easily prevent their retraction. In the sarcoma, although there are much larger vessels, the softer intervascular tissue allows them to close normally when cut through.

As a rule, pedunculated new growths arising in the nasal cavity, even when they protrude well into the pharynx, can be removed with the help of cocaine only. Myxomata, myxofibromata, and similar tumors, even when cut through rapidly, seldom bleed long, the vessels, even if fairly large, retract easily, and by cutting

Adenoid vegetation.

through slowly with the cold wire, may not bleed at all. If the source of bleeding is confined to the nasal cavity, it can be controlled, if necessary, by proper packing through the nostril.

In the nasopharynx by far the most frequent operation is for the removal of adenoid vegetations, and an

anæsthetic is generally given on account of pain. The size of the vessels entering the growth is so small and the tissues so soft that bleeding, although profuse at first, stops in a few seconds. In removing adenoid vegetations from the nasopharynx, I have for some time attempted to estimate the relative loss of blood in the quick operation with a curette and the slower removal with forceps. In the former the immediate flow is greater; with forceps the total amount lost is generally more. After curetting, the head can be thrown forward so that most of the blood comes out of the nose; with the forceps it is more difficult to keep blood from the pharynx and stomach. Fortunately, serious bleeding either at the time or secondarily is extremely rare. Excessive bleeding at the time may be readily stopped by holding gauze firmly in place against the bleeding surface.

Secondary hæmorrhage is perhaps sufficiently rare to justify a brief report of a case.

L. B., a healthy boy, twelve years old, with no previous history of bleeding, had a moderately hypertrophied pharyngeal tonsil, a large part of which I removed with one sweep of a Gottstein curette, with cocaine, but without a general anæsthetic. The amount of bleeding was not excessive. The next morning, eighteen hours after the operation, there was a slight trickling of blood from the nasopharynx, which lasted half an hour. Three hours later it began again more briskly and persisted for two hours, when I saw him. He showed constitutional signs of loss of blood, although his condition was not serious. The bleeding was stopped by packing the nasopharynx. This was removed in two days without recurrence.

A slight amount of bleeding during the twenty-four hours after removal of the pharyngeal tonsil has been reported to me occasionally by adults; proportionally much less frequently in children.

Fibromata arising from the basilar process should not, in the writer's opinion, be attacked without an anæsthetic. Not only is it often necessary to work for some time with two or more fingers in the nasopharynx to break adhesions and get the wire loop well adjusted, an extremely unpleasant proceeding for the patient, but, from the nature of the growth, the best possible preparations must be made against hæmorrhage. Even a very slow constriction by the cold wire can not be relied upon with certainty, and the seat of attachment is too far back to be sure of effectual packing through the nose. With either the hot or cold wire bleeding is liable to start before the pedicle is cut through. An effective way of preventing much bleeding in removing this growth I have found as follows: With the patient in the sitting position a string is first passed through the opposite nasal cavity and out through the mouth, and to it is attached a plug large enough to fill the whole nasopharynx. This is left outside until needed. The wire loop is then passed through the obstructed side and around the pedicle, and the tumor seized by clamp forceps, anteriorly, unless it is too large to be delivered through the

nose; otherwise posteriorly. The wire is then tightened, at first slowly, but as soon as any bleeding begins the patient's head is thrown well forward, the pedicle cut through as quickly as possible, the growth removed, the posterior packing immediately passed to the vault, and the posterior part of the nasal cavity packed through the nose with strips of gauze.

I think we may justly say that the ability to pack with gauze quickly, accurately, and firmly through the anterior nares will, more than almost anything else, give a surgeon confidence in attacking this part of the body through the natural openings.

Cases of troublesome hæmorrhage, after amygdalotomy, in adults, both at the time of operation and secondary, have been reported frequently enough to be taken out of the class of rarities. Here, again, too much reliance must not be placed on styptics and astringents. Bosworth (*Diseases of the Nose and Throat*) calls attention to the fact that in a series of cases collected by him there is no instance in which hæmorrhage seems to have been arrested by any of the ordinary styptics. Holding a styptic firmly against a bleeding surface adds compression to the styptic effect, of which the former is probably the more important. A moderate hæmorrhage is often stopped or checked by flushing with cold water, or an astringent solution, but if the bleeding looks serious we should not waste time with such uncertain agents. These are the cases which do not respond. If the bleeding point can not be found, pressure offers the best results; although this is difficult both for the surgeon and the patient. The tonsil itself is rarely if ever the source of hæmorrhage in children, but the wounding of an adherent part of the faucial pillar may give rise to troublesome bleeding. This was probably the source of the hæmorrhage in the following case, which I report, because of the rarity of reported cases of troublesome bleeding in children:

In 1891 I was asked to remove the tonsils of G. C., a strong, healthy girl of nine years of age. The tonsils were equally large, and nearly met in the median line. I cut through the left, and immediately afterward the right with the guillotine. The bleeding, which was quite profuse at first, did not stop satisfactorily, and the blood was seen to come from the right side. A saturated solution of ferric alum produced no effect. The bleeding was stopped by compressing with the finger, wrapped in gauze, with counter pressure under the angle of the jaw, maintained for half an hour. It did not recur. Subsequent examination showed that the anterior faucial pillar had been slightly wounded.

If the hæmorrhage is serious, and can not be locally controlled, the question arises of tying one of the great vessels. In an excellent paper on the surgical pathology of hæmorrhage after amygdalotomy, Delavan \* shows conclusively that tying the common carotid is uncertain on account of the collateral circulation through the circle of Willis. The ligation of the external carotid, or of both

\* *Transactions of the American Laryngological Association*, 1888.

the common and internal, should effectually shut off the blood supply from this region.

The hæmorrhage in many of the reported cases has stopped when syncope has come on, from which Delavan recommends that fainting be encouraged rather than hindered. On this account, and to get what assistance the patient can give, it is better that no anæsthetic should be given if the amygdalotome is used. The most effectual way of avoiding hæmorrhage after removal of the tonsils is in the use of a burning or slow-cutting instrument. A cold-wire *écraseur* answers this purpose admirably, but in my experience is often attended by considerable pain. Cutting through quickly with the hot wire is less painful, but does not always control hæmorrhage.

In conclusion, I will merely repeat: The surgeon, when operating in the upper respiratory tract, should always be prepared for any possible hæmorrhage by putting his patient in the best position, and by having under his hand instruments with which he can reach any part of his field of operation, perhaps even do tracheotomy or tie large vessels. Although he possibly never, during his professional career, will save the life of a patient by his forethought, he will undoubtedly do better work, and shrink less from completing what his judgment recommends, in a large number of cases.

### NASOPHARYNGEAL FIBROMATA.\*

By CHARLES M. SHIELDS, M.D.,  
RICHMOND, VA.

OF the two cases of fibroid tumors which I have to report, one occupied both nasal and pharyngeal spaces, with extensive attachments in both, while the other was distinctly a tumor of the nasopharynx:

The first was that of a young man aged twenty-three years, of Boone, N. C., sent to me February 2, 1895, by Dr. Wakefield, of Charlotte, N. C., with the following history:

For more than a year an annoying discharge from the throat, with accompanying thickness of voice and difficulty of breathing through the nose, had given to the patient and his doctor the idea that he had catarrh, for which he was treated without improvement.

Frequent small hæmorrhages and increasing difficulty in breathing impressed both that a growth was present, and he was accordingly referred to Dr. Wakefield in September, 1894, who recognized the character of the growth, and with a cold snare removed a piece as large as a walnut. The improvement following this operation was not marked, and four months afterward, in January, 1895, the patient became so much worse that he again visited Dr. Wakefield, who referred him to me with the idea that resection of the superior maxilla would be required to successfully remove the tumor, which had greatly increased in size.

I found complete nasal stenosis, the left nostril being filled with the growth, and the right occluded by

the crowding of the septum to that side by the unrelenting pressure of the tumor. In the left nostril it presented at the opening, but so completely filled the space as to prevent any determination of its attachments. I could not push a probe through either side. Examination of the pharynx with the mirror showed the growth extending down nearly to the level of the lower border of the soft palate, and apparently filling the entire postnasal space. Pressure with the finger could displace it sufficiently to make out its attachments fairly well. Its base was broad and adherent to the basilar process above and for a short distance down posteriorly on the back wall of the pharynx, as well as to the left lateral wall. It sent a short projection into the right nasal space, but so completely filled the left side as to prevent any examination with the finger there. It was red in color and unyielding to the touch. The patient had had frequent small bleedings, but only one of any considerable amount. His voice was "dead" in character, and, as a result of the pressure, he presented the typical "frog face," having associated with it the expression of apprehension, indicating the anxiety he could not conceal.

The parts were cocaineized and an attempt made to engage the tumor with a curved cold-wire snare introduced through the mouth and pushed into position with the finger; but the broad base prevented the instrument from taking hold. Then a blunt hypodermic needle was pushed in the left nostril between the growth and septum and a ten-per-cent. solution of cocaine injected, which contracted the tumor sufficiently for a filiform bougie to be pushed in and through to the throat, after considerable manipulation. To its anterior end a piece of silk was fastened, and it, in turn, to the sharply bent loop of a piece of No. 5 piano wire, which was then pulled through into and out of the mouth and shaped into a well-rounded loop. The nasal ends of the wire were carried through the cannula of the snare, and, the growth being engaged as the wire was tightened, the cannula was pulled back into the nostril until it came in contact with the pharyngeal portion of the tumor. The nut was screwed up with a pair of gasfitter's pliers for five hours, when the wire broke.

On the following day the galvano-cautery loop was carried through the nostril in the same manner and without difficulty slipped into the cut made by the cold wire. It cut its way through the remaining portion in a few moments and the separated piece was pulled down and out of the mouth with the finger. The cut base of this piece measured an inch and a quarter in its narrowest and an inch and a fifth in its widest diameter. It was found to have been continuous in front by a rather narrow attachment to the tumor in the left nasal space.

After permitting the patient to rest a few days, the latter was removed with the cautery snare. It was attached to the outer wall of the nose for about seven eighths of an inch, which was one half the distance of its length, the anterior portion being free. As a result of its pressure, most of the middle turbinated bone had been absorbed. With the relief of pressure on the septum it sprang back sufficiently for the right side of the nose to easily admit the cautery snare for the removal of the third piece, which projected into that side, but was only attached in the pharynx.

The three small pieces were remaining portions that were subsequently removed.

Iridio-platinum wire was used and was found to be more springy and to possess greater strength than the

\* Read before the American Laryngological Association at its eightieth annual congress.

platinum. It was heated from the street current through an Aloe converter and was kept at a red heat for about fifteen or twenty seconds at a time while it was drawn up; then the patient was allowed to rest for a minute or two, and the process repeated until the growth was cut through. By turning on the current for short periods, with a rest between, the wire never becomes hot enough to produce hemorrhage of any consequence.

The patient returned home, feeling well, and with free nasal respiration.

The specimen shown in alcohol has become darker in color and somewhat shrunken.

The microscope shows it to be a fibroma, containing portions of an angiomatous character.

Three weeks ago (fourteen months after the operation) the patient returned for examination, and I found a projection at the site of the old growth in the left nostril, about the size of a grain of corn, which was removed. There was also a thickening at the seat of the main tumor at the vault of the pharynx which did not present sufficiently to be engaged in a snare, and was treated by galvano-cautery application.

The second case is now under treatment, and I report it thus prematurely because of the interesting fact that it occurred in a negro woman and after the age of forty-eight.

In the matter of age, while uncommon at this period, older patients have been reported. Nélaton, Gosselin, and other earlier observers had never seen a nasopharyngeal tumor in the female. Of sixty-six cases reported by Beusch only one was in a female—a girl of fourteen. Lincoln's collection of fifty-eight did not include a single woman, and Morell Mackenzie says that instances of the disease occurring in women must be looked upon as altogether exceptional; but subsequent examination of reported cases shows that the female does not possess immunity. As regards race, however, the case is unique. I have no knowledge of any instance reported in the negro. Bosworth says: "When we consider the great frequency of uterine fibroids among the colored races, we might naturally anticipate a similar frequency of fibromata of the upper air-passages, and yet, as a matter of fact, I know of no recorded instance of a fibrous tumor of the nasopharynx occurring in a negro."

The patient, Martha Turner, of Brunswick County, Virginia, gave her age as forty-eight years, but looks older, and is a nearly pure type of the negro. She stated that three or four years ago her attention was first attracted to her throat by the thickening of her voice and sensations of pressure. For two years there had been frequent small bleedings. These symptoms increasing, she consulted her doctor, who, after several visits, noticed the pushing forward of the palate and discovered the presence of the tumor. He thrust an aspirator into it, but, finding it solid, sent her to Dr. James R. Wheat, of Richmond, who, in turn, referred her to me.

I found the growth opaque-red in color, very hard to the touch, and, at the first examination, partly covered with a little dried blood. It pushed the soft palate well forward, and, when that structure was raised, about half an inch of the tumor showed below. The finger could be passed up on either side with a little pressure, although it very well filled the entire postnasal space and

was attached both to the posterior wall of the pharynx and to its vault. At the upper part it sent a short projection into the left nostril. The patient was in good health, complained of no pain, and was only annoyed by the sense of pressure in the throat and by the frequent bleedings, which, while not of sufficient amount to weaken her, kept her always apprehensive. A small piece was cut from the lower part of the tumor and submitted to Professor J. Page Massie, pathologist to the Old Dominion Hospital, for microscopical examination, who reported it a fibroid tumor.

The broad base of the tumor, and its attachment posteriorly and above, rendered its successful engagement with the cautery snare so uncertain that I decided to try electrolysis.

For six weeks this process has been repeated at intervals of three or four days, most of the application being made with needles attached to both poles. This occasioned so much pain, however, that the method was changed to that of inserting one needle in the growth and applying the other pole on a sponge electrode to the back of the neck.

There has been some reduction in the lower part of the tumor, but not enough to make me feel much encouraged to hope for its complete removal by this means.

My experience with true fibroid tumors of the upper air-passages has been limited to the two cases reported and to a third occurring in a girl of nine years, treated three or four times by electrolysis and then passing from my observation, but subsequently reported two years later as well by her mother. I do not regard the latter case as cured by the treatment, but as one of those that we know to sometimes undergo spontaneous disappearance.

As to the treatment of these tumors, I believe that there are very few, if any, that can not now be reached through the natural passages and managed with better results than after a resection of the superior maxilla or any other preliminary operation, and resort to such measures is rarely warranted. I can not conceive of any case much more difficult to reach in this way than the first one reported, where both nasal passages were closed and the postnasal space so completely filled up, and yet persistent manipulation rendered the engagement and removal of the growth successful. The use of the ligature, chemical caustics, thermo-cautery, evulsion, etc., are not worthy of consideration in comparison with the employment of either the hot or cold snare. As to the comparative advantages of the hot and cold snare, the attending circumstances will usually determine. The cold steel wire snare has, in the estimation of some operators, the advantage of being more readily applied on account of the loop better retaining its shape. In the majority of cases, however, the finger has to be used in the postnasal space to place the wire, and then the greater elasticity of the steel is of doubtful value. In all other respects I believe the cautery snare to be preferable. It performs its work with much greater rapidity, accomplishing in a few minutes as much as the cold wire requires hours to do, and in my experience without greater pain for that length of time than attends the use of the other for the much longer period.

In employing the method of applying the current for a few seconds and allowing the patient a short rest before turning it on again, there is entire freedom from pain during the intermission and the wire does not become hot enough to occasion hæmorrhage; while at the same time we feel confident of having an instrument capable of cutting through any growth with certainty, of which fact we can not be sure in the employment of the cold snare, as is evidenced by the instances reported of the breaking of the wire or instrument in large, dense tumors, and as was my experience in its use with the first case.

Another important advantage of the hot snare is, that after being placed in position over a growth without a constricted base, the wire can at once be buried and made to take hold by being heated a few seconds during the preliminary tightening, instead of slipping off as the cold wire often does.

Finally, while removing the growth it thoroughly cauterizes every portion of the remaining stump, doing at the same time what many operators advise after other methods of removal, the burning of the base, thus securing without subsequent manipulation any advantage that may result from that practice.

#### THE RELATION OF CHRONIC DISEASES OF THE NOSE AND THROAT TO DISORDERS OF DIGESTION.\*

By THOMAS R. FRENCH, M. D.,

BROOKLYN,  
PROFESSOR OF DISEASES OF THE THROAT AND NOSE,  
LONG ISLAND COLLEGE HOSPITAL.

THE relation of chronic diseases of the throat, nose, and ear to disorders of the digestive tract is apparently not fully appreciated by the majority of even modern writers on these subjects. The relationship is not mentioned in some of the text-books, dismissed with a few words in others, and, in the writer's opinion, is not sufficiently emphasized in any. While, perhaps, the majority of writers mention dyspepsia and hepatic derangements as causes of pharyngitis, they lay, with few exceptions, but little stress upon such causes, evidently considering them of minor importance. This is shown by the liberal use of the text in describing methods for the local treatment of the disease and the omission of the suggestion for the necessity of treating the underlying cause. It is believed that a free discussion of the subject will result in a much better understanding of the degree in which diseases of the upper air tract are dependent upon digestive disorders and stimulate further researches in this direction.

The causes of chronic catarrhal pharyngitis mentioned in text-books on diseases of the throat, nose, and ear, and in monographs on pharyngitis, are very numer-

ous. The conditions and diseases which are given the most prominence, and upon which accepted authorities are more or less agreed, are: Frequent attacks of acute pharyngitis. Extension of catarrhal inflammation from the nasal passages or nasopharynx. Nasal stenosis. Nasal polypi. The excessive use of tobacco or alcohol. Improper use of the voice. Reflected irritation from a disordered digestion or diseases of the genito-urinary tract. Diseases of the glandular and nervous systems. Congested portal venous circulation. Lithæmia. Rheumatic and gouty diathesis. Dust. Smoke, in which acid fumes are inhaled, and sudden changes of hot and cold foods. While it is possible that all the above-mentioned conditions may play important parts as factors in the production or aggravation of catarrhal pharyngitis in certain cases, my belief is that in a very large majority of cases the cause of this disease will be found in some portion of the gastro-intestinal tract. Except in a few of those who have grossly abused the vocal apparatus in speaking and singing, I do not recall having examined a patient with chronic catarrhal or follicular pharyngitis in whom some disturbance of the digestion could not be detected. Indeed, I believe that some degree of indigestion in some portion of the digestive tract can be found in every case of pharyngeal catarrh, but whether the relationship of cause and effect always exists between these conditions is, perhaps, yet to be demonstrated. Nevertheless, that which I believe to be demonstrable is that one rarely, if ever, exists without the other, and this is in itself highly suggestive of a distinct relationship, and, perhaps, interdependence. It seems to me to be quite reasonable to suppose that many of the diseases and conditions mentioned as causes of pharyngeal catarrh may act indirectly as factors by first causing the disorder of the digestion.

Nasopharyngeal catarrh is often spoken of as our national disease, and I presume it is a fact that the disease is more prevalent here than in other countries. This is commonly attributed to the climate and its changeable character, to our unclean and dusty cities, and to various other conditions. In comparison with the inhabitants of other countries, we are a fast-living people, and our modes of life are highly conducive to the establishment of digestive disorders. There is probably no other country in which disturbances of the digestive function are more common than in ours. Catarrhal affections of the upper air-passages are known to be most prevalent where the climatic changes are the greatest, but I believe it will be found that catarrh of the pharynx, at least, prevails in communities where the general air of activity causes the habit of eating in haste and at irregular intervals. It is, perhaps, safe to say that the commonest error committed by the average American in ordinary daily life is that of eating hastily. Even in regions where catarrhal diseases are little known, as, for instance, the mountains in the northern part of New York State, but where the habit of eating improper food and eating rap-

\* Read before the American Laryngological Association at its eightieth annual congress.

idly prevails, especially among the working classes, I have rarely found what may be called a normal pharynx.

I refer in these remarks more particularly to the catarrhal form of pharyngitis, though I have observed many cases in which the follicular variety seemed to have been produced in the same way, or, perhaps, as the result of a pre-existing catarrhal inflammation, there being no history or appearance of lymphatic disturbances elsewhere.

With the view of assisting in determining the frequency of the concurrence of pharyngeal catarrh and gastric or intestinal indigestion, and also to show the almost universality of catarrh of the pharynx, I examined the throats and nasal cavities and asked questions in regard to the digestive function of fifty students of the Long Island College Hospital, none of whom had symptoms of sufficient importance to prompt them to seek medical advice, and most of whom were unaware that their pharynxes were not absolutely normal. Objection may be made to the selection of medical students for an investigation of this character on the ground that they live hurried and irregular lives. This is undoubtedly true, but I do not believe that they exceed in either particular the average man in large American communities. They represent a class of people living under the average conditions existing in the life of a large city, as well as that of smaller towns and villages, where the majority of these men have spent most of their lives. While, of course, the result of the examination of so small a number is not offered as in any sense conclusive, it is, nevertheless, highly significant.

Each one of the fifty was found to have a catarrh of the pharyngeal and faucial mucous membrane, varying in degree from a mild congestion to the atrophic variety of the disease. All but three gave unmistakable evidence of disturbed digestion of the stomach and intestines, fourteen of whom were the subjects of habitual constipation, and in one only was the tongue found in anything like a normal condition. Forty-five admitted that they were in the habit of eating rapidly, and often assisted the passage of the bolus by mixing fluids with the food in the mouth. Thirty-three were smokers. Sixteen had nasal obstruction, causing more or less mouth-breathing, and two were mouth-breathers at night, but without nasal obstruction.

The habit of rapid eating, which was found to be present in all but five of the students, would of itself have been sufficient to cause the disordered digestion from which they suffered. Even if the cause of the pharyngeal catarrh should be assigned to mouth-breathing in all of the eighteen cases mentioned, then only about one third of the whole number could have been caused in that way.

Thirty-three of this group were smokers. While tobacco smoke acts, no doubt, as an irritant in catarrhal diseases, as a matter of fact in the investigation of the throats of the students I did not find a greater de-

gree of congestion in those who were moderate smokers than in those who did not use the weed at all; but in those who used tobacco to excess the evidences of the habit were well marked upon the pharyngeal mucous membrane. Whether the effect upon the pharynx is direct or indirect, by causing the indigestion, it is impossible to say, but in whatever way it is produced it is quite certain that the use of tobacco alone is not sufficient to give rise to the amount of disease often seen in the throats of smokers. Many of the students who were brought up and had lived inland until they came to the seaboard to pursue their medical studies stated that there was a decided exacerbation of their catarrhal symptoms since coming to the city, but in nearly every instance they admitted that symptoms of indigestion had appeared which they had not had before, or that the symptoms which they had before were greatly augmented.

In only one of the students was the tongue found in a comparatively normal condition. A foul tongue is always accompanied by a catarrh of the pharyngeal mucous membrane, but a pharyngeal catarrh may present in connection with a tongue of nearly normal appearance.

Unless an analysis of the contents of the stomach is made, a diagnosis of a functional disorder of the stomach must be arrived at almost entirely from subjective symptoms. By the latter method we may readily fall into error as to the character of the disease, but with the aid of the stomach tube a comparatively exact diagnosis of gastric disorder can be made. With a knowledge of the stomach affection obtained in this manner the relationship of gastric disorders to catarrh of the upper air-passages can be more accurately determined.

In order to ascertain the pharyngeal condition in subjects of gastric disorder, the diagnosis of which had been made by an analysis of the stomach contents, Dr. Charles S. Fischer, of the Vanderbilt Clinic, in New York, kindly afforded me the opportunity of examining the throats and nasal passages of twenty-three of his patients whose stomach contents, after a test breakfast or dinner, he had analyzed. I am indebted to Dr. Fischer not only for his ready co-operation, but also for furnishing me with a copy of the record of each case, which contained the history, physical examination, chemical analysis, and diagnosis. A trifle more than half of the cases were neurotic in character. The remainder were mainly cases of chronic gastric catarrh. A pharyngeal catarrh, varying in degree, was found in every one of these cases. In four of the twenty-three cases the tongue presented a fairly healthy appearance. In four of the cases there was marked nasal obstruction, causing habitual mouth-breathing. In three, there was sufficient nasal obstruction to cause mouth-breathing during sleep, and in one there was habitual mouth-breathing without apparent cause. I asked Dr. Fischer to supply only female cases for my examination, and so eliminate the effects produced by the use of tobacco, and also to offset the investigation of the medical stu-

dents. While in the students' cases the contents of the stomach were not analyzed, nearly all of them presented subjective symptoms of gastric or intestinal indigestion, and, therefore, the two classes of subjects were in a general way alike. With the exception of those who smoked to excess there was no marked difference between the pharyngeal conditions in the two sexes, the degree averaging about the same in those whose stomach contents had been analyzed and those in whom the diagnosis was made from subjective symptoms. A careful study was made to determine, if possible, whether any constant pharyngeal condition existed in relation to the portion of the digestive tract affected or to the chemical character of the stomach contents in Dr. Fischer's cases, but with negative results. The appearances of the pharynx varied in cases in which the diagnosis of the digestive disorder was the same as much as in those in which it was found to be markedly different. While in two or three cases of gastric catarrh with gastroptosis the pharyngeal conditions were seen to be quite similar, the same conditions were found in the subject of a neurotic disturbance of the stomach.

Prominent among the causes of pharyngeal catarrh mentioned by modern writers is mouth-breathing due to nasal obstruction. Unquestionably, the continued mechanical irritation from cold, dirty, and dry air over the pharyngeal mucous membrane is quite sufficient to excite a considerable amount of disturbance by perverting the function of the secretory glands; but, as food must also pass through the mouth and must be hastily swallowed to free the way for air, the consequent overtaxation of the stomach and duodenum to digest food containing little or no saliva and not sufficiently disintegrated, results eventually in a chronic gastric catarrh, which, to my mind, is the more important factor in the production of the pharyngitis.

A chronic pharyngeal congestion is frequently found in the throats of speakers and singers, and it is the common belief that the disease in such cases is caused by strain of the vocal apparatus. Strain is frequently an important factor, and, at times, even the main cause, but in a large number of cases it is probable that the strain of the voice acts as an excitant of an already existing pharyngeal and laryngeal congestion which, without the strain, might never have been brought to notice.

From a clinical standpoint there is reason for the belief that functional disorders of the digestive tract are capable of producing vasomotor reflex irritation of the inferior turbinated bodies, as is evidenced by swelling of those bodies at certain times, as, for instance, on rising in the morning, and during attacks of acute gastric or duodenal catarrh. The proof of the connection is not only in the occurrence of the two affections at the same time, but also in the fact that the nasal irritation disappears after the acute indigestion has passed, or is diminished after improvement of the chronic condition of the stomach.

Beverley Robinson, in his very valuable paper on Dyspepsia as reflected in the Mucous Membrane of the Upper Air-passages, which was read before this association in 1888, suggests the probability of the mucopus from a catarrh of the upper air-passages being capable of exciting a gastric disturbance. Such a relationship of cause and effect seems to me to be highly plausible, though I am well aware that it is not generally credited. It is a mooted question as to whether the discharge from a chronic catarrhal inflammation in the nose is irritating in its character. The frequency with which catarrhal pharyngitis and laryngitis exist in association with catarrh of the nasal passages would suggest this, for it would not seem to be necessary to attribute such conditions to reflex irritation from the nose. The oropharynx will, I believe, always be found the seat of a catarrhal process when gastric catarrh is present. Laryngeal catarrh does not often exist as a result of a catarrh of the oropharynx alone, as that is a comparatively mild disorder and is not attended with much discharge; but when the nasal cavities and nasopharynx are involved in the process, because of the nature and extent of the glandular structures in those situations, the discharge is far more copious, and finds its way, to some extent, into the larynx, giving rise to a catarrhal inflammation of that cavity, but to a much greater extent is carried by gravity and the acts of swallowing into the stomach. If the catarrhal secretions flowing from the nasal passages are sufficiently irritating to excite congestion of the posterior pharyngeal wall, the mucous membrane covering the arytaenoid cartilages, and, at times, even the vocal bands, then, in all probability, are sufficiently irritating to cause a disturbance of the circulation of the mucous membrane of the stomach. But whether the discharges of mucopus from a catarrh of the upper air-passages are in themselves sufficiently irritating to excite a gastric disturbance is, perhaps, of little consequence when we consider that the process of fermentation of that material, which must occur in the stomach, would in itself be sufficient to cause irritation, not only of the mucous membrane of the stomach but of the intestinal tract as well.

The Eustachian canals and middle ears are not necessarily involved when the pharynx is the seat of catarrhal disease. Indeed, we do not know why it is that an extension into the ears occurs in one case and not in another, but it is safe to say that at least seventy-five per cent. of cases of chronic catarrh of the middle ears are caused by a catarrh of the nasopharynx. If my premises are correct, then a large proportion of the cases of middle-ear catarrh, dependent upon a pharyngitis, are indirectly caused by a gastritis or enteritis, and a proper appreciation of such an association would materially aid us in the treatment of that most persistently progressive form of ear disease.

A good voice, even for the purposes of singing and public speaking, is compatible with a moderate degree

of pharyngeal and laryngeal catarrh, but when the limits of reasonable use are exceeded, the circulation in the upper air tract is disturbed, active symptoms are presented, and loss of function ensues. It is that class of voice-users, where there is to be found an underlying catarrhal condition of the pharynx and larynx of mild degree, which we, as physicians, are most called upon to treat for impairment of the vocal function. If, as I believe, the underlying cause of the catarrh is in the majority of cases an impaired digestion, we render our patients but poor service unless we extend the treatment to parts lying far below the throat. Any treatment which has for its aim the arrest of a pharyngeal or laryngeal catarrh, partly or wholly dependent upon a disordered digestion, will surely fall short if it does not include such remedies and measures as a scientific investigation may reveal the need of to assist in the physiological and chemical performance of the digestive function.

The study of the stomach and its diseases has received a large amount of attention of late years, and, though much has yet to be learned, we are far better prepared than ever before to treat successfully the functional disorders of that viscus. An analysis of the contents of the stomach, after a test meal, made by a competent analyst, once in three or four weeks, will enable us to adopt the best course of treatment for a pharyngitis dependent upon a gastric disorder. Indigestion, even when not dependent upon organic disease of the thoracic or abdominal viscera, is commonly of such an obstinate nature that nothing short of a most careful study of each individual for causes and thorough attention to detail in the matter of diet and the administration of appropriate remedies will accomplish a cure. If the indigestion is improved or cured, and the pharyngeal disease is not eradicated, then such local remedial measures as are appropriate may be employed with markedly beneficial results.

When we consider the almost certain deterioration of the vocal powers, and the liability of the implication of the auditory apparatus from the steady progress of a pharyngeal catarrh, it behooves us to give to the study of this disease our best thought and closest scrutiny.

### A CASE OF GUNSHOT WOUND OF THE PHARYNX.\*

By D. N. RANKIN, A. M., M. D.,  
ALLEGHENY, PA.

ON October 10, 1894, I saw what I consider a very unusual case of gunshot wound of the pharynx. Two cicatrices were observable—one on each side of the neck about two inches below the lobes of the ears. Becoming interested in the case, I made further examinations, and discovered they were cicatrices from a gunshot wound. Upon looking into the throat, I found there were two

round cicatrices corresponding to the external ones, situated behind and a little below the tonsils, and between the inner ones was a cicatricial line connecting them and running directly across the posterior wall of the pharynx, this line being so superficial that the ball in its course must have merely touched the submucous tissue of the part involved.

At my request, the man wrote me the following history of the case. I will give it in his own words: "It was on the 6th day of May, 1847, when our party, consisting of myself, my servants, my physician, one dragoman, Dr. Tischendorf, my courier, and twenty-five soldiers, left Athens, taking a northwestern course to reach Missolonghi, but when we reached the foot of the Thermopylae I wanted to see the pass which was so heroically defended, 480 B. C., by Leonidas and his three hundred men against about fifty thousand Persians under Xerxes. But I was not destined to see it. On our right side rose the mountains to a height of from five hundred to two thousand feet, to our left was a great level plain. I was ahead of our cavalcade about a hundred to a hundred and fifty yards when I received a shot which penetrated my neck. The bullet went in on my right side about two inches below the lobe of the ear, and came out on the left side directly opposite the point of entrance. Of course, I dropped off my horse, and was picked up by my companions senseless. What happened during the next two months I don't know, except what I learned by hearsay afterward. The object of the shooting was robbery, and the shot fired at me was done by a very notorious brigand by the name of Kalisphenes. He was a member of a band of highway robbers, but three days after the accident happened to me they were nearly all caught, in number sixteen, leaving only four at large. All sixteen were promptly executed—hung by the neck.

"After two months' suffering (I had been removed back to Athens) I was well again, and started for Palestine. The above described has given some grounds for controversies among physicians as to the kind of a ball that was shot into my neck. Some said it was an exploding ball; others said it was not a bullet at all, but hacked or chopped lead. Since I have gained my full health, I don't care in what way or what kind of a ball was fired, but, dear sir, I assure you if the shot had come only half an inch more to the front of my face you would not be reading this report, but I would have found an early grave, for I was then twenty-one years old, and now I am sixty-one in good health."

I endeavored to learn some further particulars of the case, whether there was much hæmorrhage and difficult deglutition, or any traumatic fever, as to the means used in feeding him, etc., but was unable to obtain any facts from him further than are given above.

When we consider how vascular the mucous membrane of the pharynx is, and readily inflamed, we shall see that such inflammations, when traumatic, are peculiarly dangerous, in that they spread to the lining membrane of the larynx. In this case there was evidence of a distinct collection of connective tissue stretching across the posterior wall of the pharynx. When the tissue immediately outside the pharyngeal walls is lax, and favors the spread of effusion; when the inflammation of the pharynx is of an acute character, the effusion has been found to extend along the œsophagus,

\* Read before the American Laryngological Association at its eighteenth annual congress.

reaching the posterior mediastinum, and advancing then to the diaphragm. In the lax connective tissue between the pharynx and spine abscess is not infrequent.

Taking into consideration the immediate surroundings, the proximity to the large blood-vessels of the neck, the case at the time must have been considered a very grave one, and the man's escape from instant death was simply miraculous.

## A PENETRATING WOUND OF THE SKULL AND BRAIN.

### TREPHINING.

#### REMOVAL OF A SPLINTER OF WOOD AND A PIECE OF BONE.

### RECOVERY.

By F. U. FERGUSON, M.D.,

GALLITZIN, PA.

My aim in reporting this case is to add a point in favor of early operation in fresh and penetrating wounds of the skull and brain. Not because I think delay would have made it more difficult to find the foreign bodies, but that infection would certainly have followed such a course. It was reported that the injury was caused by a car wheel, so that the exceptional character of the wound was not looked for. Inspection and palpation did not reveal any opening that would admit a foreign body. Therefore, I expected to elevate the depression, no more.

About 2.30 p. m., February 20, 1896, G. W. R., aged thirty-five years, a master driver in a mine with a thirty-four-degree slope five hundred feet long, was sitting on a loaded car, ready to be hoisted with the trip, when two empty cars, weighing fifteen hundred pounds each, broke loose at the top and dashed down the plane. He heard them coming and warned his fellow-laborers with the exclamation, "There she comes!" at the same time making an unsuccessful effort to get to a place of safety. He gathered himself out of the wreck and with the assistance of two men stepped into an empty car and was brought out. He was then put on a stretcher and hauled home in a sled. Here he made efforts and expressed a desire to help himself. While being undressed and washed he was seized a number of times with clonic spasms of the arms and legs and would say, "There she comes!" He would fall into a sleep with stertorous breathing but could be roused, and when spoken to would talk rationally. The wounds were a V-shaped laceration of the scalp on the right side with a comminuted fracture of the skull pressing on the brain, an inverted T (1)-shaped laceration of the forehead just above the left eye, a contusion of the structures about the left eye, contusions of the top and back of the head and over the left triceps tendon. The depressed portion of the skull seemed to be not more than five eighths by an inch, and was located on the binauricular line midway between the external auditory meatus and the centre line (glabella).

The head was shaved and the wounds were grossly cleansed. Dr. Bradley and Dr. Troxell kindly consented to assist. Ether was given, but the vomiting was so annoying that chloroform was used to finish the anæsthesia. I then made an attempt to remove the pieces of

bone, but this was followed by so much hæmorrhage that it was decided to enlarge the wound, which was done with a five-eighth-inch trephine and a pair of bone forceps. After the pieces of bone were picked out with hæmostatic forceps the opening in the skull measured about five eighths by an inch and three quarters. The blood welled up freely out of the lacerated tissues so that a small probe was used to explore the wound; a solid was felt and, after some searching, I succeeded in catching the object with a hæmostatic forceps, and with considerable force withdrew a splinter of wood that had penetrated the brain transversely. A piece of bone, a fragment of the inner table, a quarter by an inch and a half, also was found in the track of the wood. The splinter of wood measured an inch and three quarters in length; its large end, which entered the brain first, was pyramidal in shape; the ascending angles measured three eighths and half an inch, the perpendicular a quarter, and the base five eighths of an inch. It had come from the mortised end of a piece of three-by-four-inch oak scantling (one side of the brake lever, which is held to its felly by the tenoned ends of a like piece of wood). Hair and blood were found later on the piece and the splinter fitted to its former place. The bleeding was stopped with gauze compresses dipped in hot water and cooled until they could be comfortably handled. He was put to bed with hot-water bottles, and although the shock was considerable he rallied well. No sutures were used in the dura or scalp, but the laceration above the eye was closed with three sutures. The dressing—a pad of iodoform gauze—was laid over the pulsating brain, and the flap dropped on the gauze; then a pad of bichloride gauze held in place with a recurrent bandage. All was completed at five o'clock, about two hours and a half after the injury.

Two hours later I examined the muscles for paralysis. The injury to the brain being on the right side, there was complete motor paralysis of the left side of the body. The left side of the face and all of the left upper extremity did not respond to a pin prick. The left leg was sensitive; a pin prick in the left would cause the right leg to be pulled out of the way. The urine was drawn at 10 p. m., and twice daily thereafter for seventeen days. During the first night and the next day vomiting was frequent; a piece of corn-cob which he had in his mouth at the time he was struck was in the vomitus. Urine and fæces were passed involuntarily the first night. The wound was dressed daily for seventeen days in the manner described above. Sterilized water containing two per cent. of boric acid was used to flush the wound. At least a drachm of brain tissue came out at each of the first two dressings, and for four or five days brain *débris* and particles of coal came out on the gauze. No pus was seen and the wound granulated full in eighteen days, when the flap was let down, dusted with acetanilide, and not opened until union was complete. The temperature was 99.5° on the first morning after, and 100° in the evening; 100° on the second morning, and 99° in the evening; it did not rise above 99° after. The pulse was 78 and 84 respectively on the morning and evening of the first day after; on the morning and evening of the second day, 72 and 60 respectively. Its frequency diminished for six days, when it reached 48, and continued between 48 and 56 until March 9th. On this date it was 54 in the morning before rising and 72 in the evening, the patient sitting up. It went along at this rate until March 11th, when before rising it was 60.

March 12th.—Patient sitting up, evening pulse 78.

13th.—Patient in bed, 79. After this it was 72 when counted. Calomel was given daily, but the bowels only moved every four or five days. It was necessary to give morphine three or four times only. The appetite was very poor; some days we could force only eight ounces of milk. He drank water freely notwithstanding more or less dysphagia. For three weeks we had to coax him to take food. Doubtless the small quantity of food had something to do with the slow heart. The paralysis gradually passed off. On the first day after the injury he had some motion in the left leg. A pin prick was felt in the arm on the sixth day and motion was noticed on the seventh; this was followed day by day with a resumption of muscular functions, first the wrist, then the little and ring finger muscles, finally those of the thumb, index, and middle fingers. Sensation always preceded motion. The galvanic current was applied frequently during the fourth and fifth weeks; the patient thought the muscles had better tone after the applications. The contusion on the left arm received no attention. Three weeks after the injury I noticed the forearm could not be completely flexed. Force caused pain at the point where the arm was injured. The arm was forced into flexion and the adhesions broke up with a snap. On the 19th of May he returned to his work, but the hand had not yet its normal strength and the face still felt a "little stiff."

## EPITHELIOMA OF THE SOFT PALATE, REMOVED BY INJECTIONS OF LIQUOR POTASSÆ.\*

By THOMAS HUBBARD, M.D.,  
TOLEDO, OHIO.

A GENTLEMAN about fifty years of age suffered for several months from painful excoriations, caused apparently by the posterior edge of the upper dental plate. During the fall of 1893 there gradually developed a flat, tabular tumor, nearly as large as a nickel piece and about twice as thick. It was partly in the soft palate and partly in the anterior pillar of the fauces on the right side. It was very painful, and all faucial movements were restricted. There was an exuberant growth of papillomatous excrescences over the buccal surface of the cheek. He became addicted to the cocaine habit, which still further lowered his vitality. For this he tried sanatorium life and succeeded in temporarily breaking the habit. During the winter and spring of 1894 he subsisted on milk, oatmeal, and ice cream. He lost about forty-five pounds during the year. In the early summer of 1894 he relapsed to the former habit through the use of "Birney's catarrh snuff," which I accidentally discovered in his possession when I took charge of the case in August, 1894, and subsequently found to contain about fifteen grains of cocaine to the ounce of powder. It took several weeks to get him into condition for operation.

In October active treatment was begun. Injections of liquor potassæ were administered by means of an asbestos-packed syringe with a curved platinum needle. The pain was not severe, and by the use of cotton swabs and a very dilute acetic-acid solution the mucous membrane around the growth was protected.

At the second operation I injected quite deeply, carrying the point of the needle well beneath the tumor from five points at its circumference, depositing a portion of a drop with each puncture. A small artery was eroded, and the mass suddenly puffed up, but there was no hemorrhage. Inflammatory reaction was kept down by iced drinks, and only a bromide sedative was required. In three days the whole mass sloughed away, leaving a hole as large as a half cherry. This healed readily, and on two subsequent occasions small masses of proliferating granular or papillomatous tissue around the edges were injected and destroyed. The papillomatous masses in the right cheek were curetted and thoroughly destroyed by stick potash, care being taken to avoid the orifice of Stenson's duct.

The improvement following the subsidence of painful deglutition was remarkable, the patient gaining more than forty pounds in a few months.

In April, 1896, I examined him carefully and found the following condition: There were some papillomatous masses over the right cheek, caused probably by the dental plate and teeth, which he had resumed wearing soon after the tumor had been destroyed. At the former location of the tumor there was a dense, firm cicatricial mass, about as large as a nickel, which drew the uvula well over to the right side. There was no return of the tumor, and the function of the soft palate was not materially interfered with. For more than a year he had been in excellent health and had been at his office regularly.

In March, 1896, he had noticed a condition of progressive dyspnoea. Examination of the thoracic viscera revealed dullness over the base of the left lung and a pronounced cardiac murmur, diagnosed as mitral insufficiency. Subsequently, albumin, but no casts, was found in the urine by his family physician. From about May 1st he declined rapidly, all heart sounds becoming more faint and the dyspnoea increasing. There was considerable general anasarca. On June 1st he expired suddenly.

We were granted a necropsy. The dyspnoea was in part accounted for by a serous effusion in both pleural sacs, being more extensive on the right, but especially by degeneration and softening of the cardiac structures. The hypertrophied muscle of the left ventricle was so soft and friable that it was easily crushed between the thumb and finger. One segment of the mitral valve was completely tied down by adhesions. No atheromatous deposits were found. The kidneys showed indications of a subacute inflammatory condition, being somewhat larger than normal, with adherent capsules, and areas of fibroid contraction.

It may be interesting to add that in his youth he had had quite severe pulmonary hemorrhages, and was for several years thought to have pulmonary tuberculosis. We found both apices adherent, and over the right was a depressed cicatrix with a firm fibrous nodule, about an inch and a half by half an inch in size. There were no indications that the tuberculous disease was again in an active state, or that it had anything to do with the pleural effusion. The condition of the fauces was the same as previously noted. All the other organs were normal.

Prior to the operation a small piece of the growth was removed with scissors. This was sectioned and mounted, and the author is gratified to be able to quote the opinion of Dr. Jonathan Wright, of Brooklyn, as to the definite character of the tumor. "The surface epithelium is thickened, forming many layers with dis-

\* Read before the American Laryngological Association at its eighteenth annual congress.

tinect papillæ formation. Here and there are some large cells with cloudy contents and oval nuclei. The connective tissue is scanty, as are the blood-vessels. It is loosely arranged, and here and there in it are nests of epithelial cells, all apparently entirely unconnected with the surface epithelium, and in close proximity to some dilated blood-vessels. In those nests are some of the large cells noted in the surface epithelium. From absence of much inflammatory tissue, from the few 'cancer nests,' and the absence of distinct carcinomatous figures, I should think it of slow growth and not very malignant, but distinctly an epithelioma."

The sequence of pathological conditions was probably as follows: The valvular defect, cause not known, encouraged cardiac hypertrophy. Malnutrition from prolonged throat disease caused degeneration of the hypertrophied heart muscle, and the valvular defect thus became a prominent factor in his decline. The renal disorder was probably a late complication.

The papillomatous growth, which covered an area in the cheek about half an inch in diameter, involving also the mucous membrane over the alveolar process where it was in contact with the cheek, suggests a very decided abnormal tendency toward proliferation of the epithelial cells of the mucous membrane. There were at the same time areas of excoriated membrane over the soft palate. Transplantation of proliferating cells is a possibility. This is speculative, since both conditions may have originated from irritation from the dental plate or from smoking, but we are warranted in calling attention to the use of caustics as the superior method of removing such growths as are here described. There is no doubt but that the surgeon's knife is occasionally a medium of transplantation of cancer cells, and in view of this, and for other reasons, destructive chemical agents may often be used to great advantage.

## Therapeutical Notes.

**Sodium Chlorate in the Palliative Treatment of Cancer of the Uterus.**—Boucher, of Rouen, according to the *Therapeutische Wochenschrift* for August 16, 1896, prescribes the following:

R Sodium chlorate..... 2 parts;  
Distilled water..... 10 "  
Syrup of orange flowers..... 3 "

M. At first two "spoonfuls" (whether teaspoonfuls or tablespoonfuls is not stated) are to be taken in twenty-four hours, and the daily amount is to be increased gradually to eight "spoonfuls."

The following powder is applied on intracervical tampons:

R Sodium chlorate, 1 of each.... 2 parts;  
Bismuth subnitrate, 1  
Iodoform..... 1 part.

M. In addition, the vagina is irrigated daily with a solution of a hundred and fifty grains of sodium chlorate in a quart of boiled water. It is said that this treatment

often prolongs life for a year and makes it reasonably tolerable.

**The Treatment of Lupus with Maragliano's Tubercle-antitoxine Serum.**—Terrill (*Gazzetta degli ospedali*, July 12, 1896; *Therapeutische Wochenschrift*, August 9, 1896) has used this serum on two young subjects one of whom had lupus of the foot and the other lupus of the hand. The first one received, in all, a hundred and seven cubic centimetres of the serum (at first one cubic centimetre every second day, then five cubic centimetres every third day; the second got twenty-five cubic centimetres (five every third day), and was also treated topically with the serum. In each case the result was very gratifying, although a perfect cure did not take place. The infiltration subsided and the joints became movable. The local application of the serum was founded on its direct destructive action on the bacillus, as was shown by the healing of a tuberculous anal fistula after local injections of it.

**The Palliative Treatment of Cancer of the Cervix Uteri.**—At a recent meeting of the Lancetan Society of the Hospitals of Rome (*Wiener klinische Rundschau*, August 9, 1896) Dr. Marocco reported good results from tamponing with gauze impregnated with tannin, iodoform (ten per cent.), and powdered quinine.

**Ichthylol in the Treatment of Whooping-cough.**—Dr. L. Maestro (*Pediatrics*, June, 1896; *Therapeutische Wochenschrift*, August 9, 1896) reports experience with the ichthylol treatment of whooping-cough in Professor Cervasato's clinic in Padua. The drug was given in pills in daily amounts of from three quarters of a grain to three grains, according to the child's age, rapidly increased to from nine to fifteen grains. Mitigation of the frequency and severity of the paroxysms and shortening of the course of the disease followed in every case. The ichthylol caused no untoward symptoms; on the contrary, it bettered the general condition. Maestro regards it as one of the best remedies for whooping-cough.

**The Calomel Treatment of Hæmorrhoids.**—Dr. H. Naegeli-Akerblom (*Allgemeine medicinische Central-Zeitung*, 1896, No. 64; *Therapeutische Wochenschrift*, August 16, 1896), acting on the suggestion of Professor Massini, of Basel, has treated a number of cases of hæmorrhoids, large and small, internal and external, with an ointment composed of one part of calomel and nine parts of vaseline, and states that in none of them has he felt obliged to operate. In most cases the itching subsides completely. The suggestion is made that the calomel is changed into corrosive sublimate and acts as a caustic, and consequently should be used with caution if there is ulceration.

**Irritation of the Bladder from Sodium Bicarbonate.**—In a Paris thesis (*Centralblatt für Chirurgie*, August 15, 1896) Debains presents a study of this subject. It seems that Mathieu first called attention to the fact that the prolonged use of sodium bicarbonate sometimes gave rise to painful and frequent urination and even hæmaturia. These symptoms are of no grave import, for they subside at once when the use of the drug is stopped.

**Basic Orexine in the Treatment of the Vomiting of Pregnancy.**—Reich (*Centralblatt für Gynäkologie*, August 15, 1896) adds one case to the four reported by Frommel, in 1893, of the successful employment of basic orexine in the treatment of obstinate vomiting of pregnancy. He gave it in doses of four grains and a half,

in capsules, three times a day. The first and second doses were rejected in the course of a few hours, but after the third there was no more vomiting. The use of the remedy was continued for three days. Among the drugs that had previously been employed without success were nux vomica, potassium bromide, chloroform with tincture of iodine, and cocaine. The patient, who had lost sixteen pounds, recovered her weight in four days. With the exception of severe burning in the mouth after vomiting the first and second doses, she experienced no unpleasant effects.

#### Bromoform in the Treatment of Whooping-cough.—

The *Lyon médical* for August 16th publishes the following formula, which appeared in the August number of the *Revue mensuelle des maladies de l'enfance*:

R Bromoform,.....	48 drops;
Oil of sweet almonds, { each.....	22½ grains;
Gum arabic,.....	
Cherry-laurel water.....	60 “
Distilled water, enough to make... 3.75 ounces.	

The bromoform and the oil are mixed first and thoroughly shaken, after which the rest is added. One teaspoonful contains two drops of bromoform.

#### Sulphate of Duboisine as a Means of combating the Repugnance for Food in Patients with General Paralysis.

—At a recent meeting of the Congrès des médecins aliénistes et neurologistes de France et des pays de langue française, a report of which is published in the *Presse médicale* for August 15th, M. Francotte stated that he had employed a forty-per-cent. solution of duboisine in doses varying from a quarter to a third of a Pravaz syringe. In persons with general paralysis there had been a cessation of the repugnance to food. On the other hand, in the insane, the duboisine had been ineffectual. M. Francotte said that he could come to no definite conclusion, and he hoped to see his observations verified by others.

**An Application for Inflammatory Toothache.**—Dr. S. Wotjoff (*Therapeutische Monatshefte*, April, 1896; *Wiener klinische Rundschau*, August 23, 1896) recommends this mixture for toothache depending on inflammation of the dental pulp:

R Cocaine hydrochloride.....	1 part;
Camphor,.....	
Chloral hydrate, { each.....	50 parts.

M. Rub enough water with the mixture to make a clear solution, rinse the mouth with it, and insert into the cavity of the tooth a bit of cotton wet with the solution, to be retained for twenty-four hours.

**A Lotion for Pruritus.**—Dr. C. Boeck (*Monatshefte für praktische Dermatologie*, 1895, No. 3; *Wiener klinische Rundschau*, August 23, 1896) recommends the following formula:

R Talc,.....	50 parts;
Starch, { each.....	
Glycerin.....	20 “
Lead water.....	100 “

M. It is to be diluted with an equal amount of water when it is used. It is particularly useful in cases of itching associated with a foul discharge.

**The Treatment of Headache.**—The *Gazette hebdomadaire de médecine et de chirurgie* for August 23d recommends the following method, which is attributed to Dr. Critzmann: To diminish the hyperæsthesia, the painful region should be sprayed with Seltzer water, and immediately afterward energetic bilateral compression should be practised on the temples. Every two hours the pa-

tient should take a capsule containing the following mixture:

R Antipyrine.....	8 grains;
Sparteine sulphate.....	0.3 grain;
Caffeine citrate.....	1.75 “

M.

Four of these capsules may be taken, even if the pain has completely disappeared. If there is gastric intolerance, the mixture may be administered in the form of an enema. This treatment arrests the attack of headache, and often enables the patient to attend to his occupation; it suppresses the pain and the nausea, and renders unnecessary the consequent rest in bed to which such patients are apt to be condemned.

**Hyperidrosis.**—The *Revue internationale de médecine et de chirurgie* for August 25th states that M. Hensser has employed the following mixture with successful results:

R Formic acid,.....	5 parts;
Chloral,.....	
Alcohol.....	89 “
Balsam of Peru.....	1 part.

M.

This mixture is applied with a tampon of cotton. In generalized hyperidrosis it is well to spray the skin with it. When the localized sweating is particularly rebellious, M. Hensser adds trichloroacetic acid to this mixture in the proportion of one per cent. For combating sweating of the feet in soldiers, he recommends the employment of a one- or two-per-cent. solution of trichloroacetic acid. Unfortunately, it has the inconvenience of changing the color of any material with which it comes in contact.

**An Astringent and Antiseptic Injection for Uterine Leucorrhœa.**—The *Gazette hebdomadaire de médecine et de chirurgie* for August 20th publishes the following formula, which is attributed to M. A. Bustillo Lirola:

R Tannic acid.....	900 grains;
Pure alcohol,.....	450 “
Creosote, { each.....	
Distilled water.....	7.5 ounces.

M.

From three to four injections a day are to be taken, for each of which a dessertspoonful of the solution is to be diluted with a pint of warm water.

**The Treatment of Enteroptosis with Yeast.**—The *Presse médicale* for August 19th publishes an abstract of an article from the *Münchener medicinische Wochenschrift* for July 7th in which the author states that he has made use of this treatment in a large number of cases with successful results. Every day a small quantity of baker's yeast, of about the size of a bean, is given, and the fermentation provoked by the yeast causes a certain degree of flatulence which holds and immobilizes the intestine. Occasionally this flatulence becomes too great and provokes a feeling of distention; in this case the quantity of yeast must be diminished.

In a general manner, this treatment gives the patients a sensation of comfort. They are no longer inconvenienced with flatus, and this is attributed by the author to the peculiar action on the intestine of the carbonic acid which, under the influence of the yeast, is developed in the digestive tract. The stools become regular and abundant, and the distention of the intestine carries the aorta away from the abdominal wall so that the patients do not feel the beating of this vessel. Finally, the appetite becomes better and large quantities of food can be taken without difficulty.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 12, 1896.

IS THERE A PHYSIOLOGICAL ALBUMINURIA?

At the recent French Congress of Internal Medicine, a report of which appears in the *Gazette médicale de Paris* for August 22d, several subjects of interest in renal pathology were considered in a paper by M. Arnozan. Among them was the question of the existence of an albuminuria having no significance as to the state of the person's health.

M. Arnozan stated that certain authors, Senator in particular, admitted that albumin was a normal element of urine, but this opinion was rejected at the present day by the majority of chemists and physicians. Others, such as Capitan, Leube, and Stewart, thought that albumin might exist in the urine accidentally and in a transitory manner, that is to say, that there was a physiological albuminuria independent of all diseased conditions. It was true, said M. Arnozan, that many persons enjoyed good health and led an active and even laborious life, although there was albumin in the urine; it was a mistake, however, to suppose absolutely that these persons had no defect. It was notable that this albuminuria called physiological was influenced by the same causes, such as menstruation, muscular work, cold baths, and digestion, which influenced the albuminuria known as pathological.

Certain advocates of the theory of accidental albuminuria, said M. Arnozan, even went so far as to say that this albuminuria was only the first stage or the onset of certain forms of nephritis, of the small red contracted kidney in particular. Therefore we must admit, with Lécorché and Talamon, that all albuminuria was pathological.

The pathogeny of albuminuria was extremely complex and authors had expressed many hypotheses on the subject. Gubler and Robin thought that, in its chronic forms at least, albuminuria was the result of an alteration of the blood. According to this theory, the blood being first diseased, the kidney was affected subsequently and allowed the normal albumin of the serum to filter through it. Other authors had admitted that the presence of albumin indicated important changes in the blood pressure, that there was an excess of tension, as in the albuminuria of cardiac troubles, or else that there

was, on the contrary, a slackening of the course of the blood. Afterward it was admitted that lesions of the epithelium, of the glomeruli, and of the convoluted tubules existed. M. Arnozan himself had ascertained that all the inflamed epithelia exuded more or less large quantities of albumin. The kidney, in allowing the albumin to pass, only conformed to the rule. He thought, then, that in acute nephritis the albumin must be considered as a simple product of inflammation. It resulted rather from an exudation than from a transudation. Proofs of these facts existed, said the author. First, formed elements of the blood were found besides inflammatory albumins; afterward, in degenerative lesions, such as cancer of the kidney, albumin might be absent. Finally, according to Ott, the emission of nucleo-albumin often accompanied the emission of serine or albumin properly so called. Now, the nucleo-albumin seemed to belong to the albuminurias which proceeded from disorganization of the epithelia.

Consequently, said M. Arnozan, albuminuria might proceed from an alteration of the albumins of the blood, from an affection of the renal circulation, from an epithelial lesion of the kidney, or from an inflammatory exudation discharged at the surface of the canaliculi. But this albumin did not carry with it the characteristics of its origin, and, as it could not give any information as to the extent of the lesions or as to their degree of curability, it followed that it was only a relative element in prognosis. It assumed, however, a greater prognostic importance when the study of the formed elements of the blood in the urine was joined to that of the urinary toxicity. M. Denigès, said M. Arnozan, had shown that when leucocytes existed in albuminous urine their number seemed to vary with the quantity of albumin eliminated. On the other hand, it was known that the less toxic the urine was the graver was the prognosis. Finally, we must also take into consideration the function of the kidney as a gland of internal secretion. Researches, however, on this point, said M. Arnozan, were as yet insufficient.

ADENITIS OF THE NECK AND CARIOUS TEETH.

A GERMAN surgeon, Dr. Starck (*Beiträge zur klinische Chirurgie*, xvi, 1; *Centralblatt für Chirurgie*, August 22, 1896), has been looking into the matter of the connection between simple and tuberculous chronic cervical adenitis and carious teeth. With reference to this point, he has examined upward of a hundred children between three and twelve years old. Excluding all cases in which any other possible cause could be assigned for the glandular swellings, such as an hereditary

tuberculous tendency, recent attacks of measles, scarlet fever, diphtheria, or angina, and the like, he has found that in forty-one per cent. of the children affected with chronic cervical adenitis no other cause could be recognized than dental caries.

Carious teeth, then, are to be set down as among the commonest avenues of infection in children, along with tonsillar tuberculosis. In five cases, of which the histories are given, unilateral tuberculosis of the submaxillary glands developed in immediate connection with toothache. In one of these cases two carious teeth were extracted, and tubercle bacilli came with them. In only one case was the tissue between the roots of the teeth found to be tuberculous.

Dr. Starck draws a practical lesson from his observations to the effect that surgeons should make it a rule, whenever they operate for tuberculous glands of the neck, to extract any carious teeth that may be present, since otherwise they may prove a source of relapse. Moreover, it follows from the importance of carious teeth as points of entrance for infection, especially in children, that endeavors to make adequate care of the teeth and mouth obligatory in schools should have the zealous aid of physicians.

### MINOR PARAGRAPHS.

#### THE NEW JOURNAL OF MEDICAL HISTORY AND GEOGRAPHY.

THE first number of *Janus*, the new journal of medical history and geography the prospectus of which we noticed some months ago, has made its appearance. It contains an introduction entitled *Janus Redivivus* by Professor Stokvis, printed in French, and nine other articles in French, German, and English. The American members of the editorial staff are Professor Osler, of Baltimore, and Surgeon-General Sternberg, of the army. *Janus* promises to be a very interesting and valuable periodical. It is published in Amsterdam.

#### THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

As will be seen by the orders which we publish elsewhere in this issue, Dr. John B. Hamilton, of Chicago, formerly the surgeon-general of the Marine-Hospital Service and now a surgeon in that service, has been ordered to San Francisco. As he is the editor of the *Journal of the American Medical Association*, it is to be feared that he will be very much hampered in his editorial work if he has to be stationed so far away from the seat of the *Journal's* publication. For the sake of the *Journal*, which he has much improved, we hope that the welfare of the Marine-Hospital Service will not call for Dr. Hamilton's prolonged absence from Chicago.

### ITEMS.

**The Buffalo Academy of Medicine.**—At the last meeting of the Section in Surgery, on Tuesday, the 1st inst., the

special order for the evening was a paper on The Digestive Ferments, with Special Reference to their Use in Surgery, by Dr. A. L. Benedict, and one entitled Eucaine, the New Local Anæsthetic, by Dr. Y. C. Clemensha. At the last meeting of the Section in Medicine, on Tuesday evening, the 8th inst., a paper on The Bacteriology of Diphtheria was read by Dr. W. G. Bissell, and a Report of the Antitoxine Treatment of Diphtheria in Buffalo was presented by Dr. Irving M. Snow.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 8, 1896 :

DISEASES.	Week ending Sept. 1.		Week ending Sept. 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	21	6	35	6
Scarlet fever.....	26	2	22	3
Cerebro-spinal meningitis. . .	1	0	0	0
Measles.....	26	1	24	3
Diphtheria.....	142	25	132	27
Tuberculosis.....	192	107	151	83

**The Trip to Mexico.**—The New-York and Cuba Mail Steamship Company has issued the following circular, dated August 1st:

"This company has been asked to make arrangements in connection with the transportation of delegates to the Pan-American Medical Congress, to be held in the City of Mexico, November 16th, 17th, 18th, and 19th of the present year, at which it is expected a large representation of the medical fraternity of the United States will be present. The time of the year has been especially well selected, and the steamers offer every facility for speedy and comfortable travel. They are large steel boats, ranging from 3,500 to 4,500 tons, equipped with every modern appliance for safety, lighted with electricity, and with an unexcelled cuisine. The route is *via* Havana, Cuba, thence to either Vera Cruz or Tampico, Mexico, and by rail to the City of Mexico. It is an ideal voyage into tropical seas and a country of romance, history, and mystery—the land of song and sunshine—never to be forgotten. Excursion tickets for this trip will be sold at a reduced rate, or, if desired, arrangements will be made to issue tickets by which the holder can return overland by rail from Mexico or going overland, can return by steamer. It is an opportunity to make a very delightful trip at a reduced rate, and to combine the best features of tropical travel. Appreciating the advantages to be derived from carrying a fair representation of medical men over the route, this company is prepared to offer every inducement for their comfort and enjoyment."

**Free Silver and Medical Colleges.**—An esteemed correspondent who occupies a chair in one of the St. Louis medical colleges says, in a letter recently received: "Students are coming in fast. We have more present than ever before in the history of our institution, but I must say this silver movement has greatly affected our finances. I am astounded when I see sensible men, or men who by every manner and means should be sensible, cutting their own throats in this wild and unreasonable bypath of political economy. It has paralyzed all of our interests, even gone into medical life with its paralyzing influence."

**The Polish Physicians of Chicago.**—On the 29th of August the Polish physicians of Chicago organized a society which is to be known by the name of Towarzystwo Lekarzy Polskich (Polish Physicians' Society). It includes the following members: Dr. E. Czerniewski, Dr. M. Dowiat, Dr. M. Orgler-Kaczorowska, Dr. J. P. Kaczorowski, Dr. M. P. Kossakowski, Dr. W. Kuflewski, Dr. J. Piszczak, Dr. W. J. Sieminiowicz, Dr. W. Statkiewicz, Dr. B. F. Strzyzewski, Dr. J. Ziolkowski, and Dr. R. L. Lande, of Milwaukee. The society is to be for purely scientific purposes. The first regular meeting will take place at the residence of Dr. W. Statkiewicz, No. 3315 Laurel Street, on Saturday, the 12th inst.

**The New York State Association of Railroad Surgeons** will hold its annual meeting in the New York Academy of Medicine's building on November 17th, under the presidency of Dr. C. S. Parkhill, of Hornellsville.

**Changes of Address.**—Dr. W. C. Allen, to No. 1518 North Tenth Street, Philadelphia; Dr. A. J. Dunne, from Springfield, Massachusetts, to No. 124 North Street, Pittsfield, Massachusetts.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 30 to September 5, 1896:*

**REYNOLDS, FREDERICK P.**, First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Clark, Texas, and ordered to Fort McIntosh, Texas, for duty, relieving **WOODSON, ROBERT S.**, First Lieutenant and Assistant Surgeon. Lieutenant Woodson, on being thus relieved, is ordered to Jackson Barracks, Louisiana, for duty at that station, relieving **POWELL, JUNIUS**, Captain and Assistant Surgeon. Captain Powell, on being thus relieved, will report to the president of the examining board appointed to meet at the office of the Surgeon General of the Army, for examination for promotion, and, upon conclusion of examination, is ordered to Fort Riley, Kansas, for duty, relieving **TURRELL, HENRY S.**, Major and Surgeon. Major Turrell, on being thus relieved from duty at Fort Riley, is ordered to Willett's Point, N. Y., for duty, relieving **KOEPFER, EGON A.**, Major and Surgeon. Major Koepfer, on being thus relieved, is ordered to Fort Crook, Nebraska, for duty.

**WOODHULL, ALFRED A.**, Lieutenant Colonel and Deputy Surgeon General, is granted leave of absence for one month and ten days, to take effect about September 15th.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending September 5, 1896:*

**STITT, F. R.**, Passed Assistant Surgeon. Ordered to duty in the Bureau of Medicine and Surgery.

**LOWNDES, C. H. T.**, Passed Assistant Surgeon. Detached from the Naval Hospital, Philadelphia, and ordered to the Washington Navy Yard.

**MORRIS, L.**, Assistant Surgeon. Ordered to the Naval Hospital, Philadelphia.

**COSTIGAN, G. D.**, Assistant Surgeon. Ordered to the Naval Laboratory for instruction.

#### Society Meetings for the Coming Week:

**MONDAY, September 14th:** New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private); New York Ophthalmological Society (private); Boston Society for Medical Improvement; Microscopical Club of the Buffalo Society of Natural Sciences; Gynæcological Society of Boston; Burlington, Vermont, Medical and Surgical Club; Norwalk, Connecticut, Medical Society (private).

**TUESDAY, September 15th:** Mississippi Valley Medical Association (first day—St. Paul); New York Academy of Medicine (Section in General Medicine); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Society of the County of Kings, N. Y.; Buffalo Academy of Medicine (Section in Pathology); Baltimore Academy of Medicine.

**WEDNESDAY, September 16th:** Mississippi Valley Medical Association (second day); Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

**THURSDAY, September 17th:** Mississippi Valley Medical Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Massachusetts, Society for Medical Improvement (private).

**FRIDAY, September 18th:** Mississippi Valley Medical Association (fourth day); New York Academy of Medicine; Brooklyn Medical Society; St. Louis Academy of

Medical and Surgical Sciences; Baltimore Clinical Society; Chicago Gynæcological Society.

**SATURDAY, September 19th:** Clinical Society of the New York Post-graduate Medical School and Hospital; St. Louis Medical Society.

## Births, Marriages, and Deaths.

### Born.

**THOMSON.**—In New Haven, on Wednesday, September 2d, to Dr. and Mrs. Edmund S. Thomson, a daughter.

### Married.

**MEAD—MILLS.**—In Larchmont, N. Y., on Wednesday, September 9th, Dr. Edward I. Mead, of Greenwich, Connecticut, and Miss Mary Mills.

### Died.

**BUCHANAN.**—In New York, on Wednesday, September 2d, Dr. Alexander Buchanan, in the sixty-sixth year of his age.

**DEYO.**—In Kingston, N. Y., on Monday, August 31st, Dr. Charles W. Deyo, aged fifty-seven years.

**FARRINGTON.**—In New York, on Monday, September 7th, Dr. Edward S. Farrington, in the thirty-first year of his age.

**GUERIN.**—In Summerville, South Carolina, on Friday, September 4th, Dr. H. C. Guerin, in the sixty-ninth year of his age.

**HOPKINS.**—In New York, on Friday, August 21st, Dr. John Louis Hopkins, in the thirty-fifth year of his age.

**SHURLY.**—In Rhinebeck, N. Y., on Saturday, August 22d, Mrs. Elizabeth Shurly, wife of Dr. E. L. Shurly, of Detroit.

**MCLAURY.**—In New York, on Tuesday, September 8th, Dr. William M. McLaury, in the sixty-seventh year of his age.

## Letters to the Editor.

**BALSAM OF PERU AND BALSAM OF COPAIBA IN THE TREATMENT OF SCABIES, AND ERRORS IN MEDICAL LITERATURE.**

NEW YORK, August 29, 1896.

To the Editor of the New York Medical Journal:

SIR: In the controversy between Dr. Campbell and Dr. Coggeshall as to which balsam is meant in Waring's *Therapeutics* and which of the balsams is the remedy in scabies, it is my positive opinion that it is balsam of Peru and not balsam of copaiba. If Dr. Coggeshall's copy of Waring's *Therapeutics* has it balsam of copaiba, it is simply a slip of the pen or typographical error.

My opinion is based on the following three points:

1. While Peruvian balsam has for many decades been used in dermatological practice, copaiba has not been used in a single skin disease that I am aware of. The power of balsam of Peru to allay pruritus, due no matter to what cause, and its parasitocidal properties (due to its containing benzoic and cinnamic acids, styrol, toluol, etc.) are or should be well known to every physician.

2. Dr. Coggeshall quotes: "Each child was first washed with soap and water and then rubbed all over twice daily with the balsam." Now, if a child were

rubbed twice daily "all over" with copaiba, it would, I am sure, get such a severe, intractable dermatitis that the cure would be immeasurably worse than the disease—if a cure was affected, which I doubt very much, as the bactericidal and parasitocidal properties of copaiba have been shown to be absolutely nil.

3. I have not used and do not intend to use copaiba in scabies, but I have used balsam of Peru in that affection a number of times with excellent results. Though, perhaps, irrelevant to the subject of this letter, I will give in brief my treatment of scabies, which has not failed in a single instance. The patient is anointed with *sapo viridis*, which is left on for one to two hours. A hot bath of half an hour to an hour's duration is ordered, during which he is rubbed with tar or tar soap; after the bath (which is always ordered in the evening) the whole body is thoroughly rubbed with the following ointment:

R Sublimed sulphur.....	15 parts;
Potassium carbonate.....	5 "
Balsam of Peru.....	30 "
Lanolin.....	150 "

M.

This ointment is left on overnight, in the morning a bath is taken, and in nine cases out of ten the patient is completely free from his *Acari scabiei*. In some cases a second treatment is necessary. I tried the ointment without the balsam, but the results were not so satisfactory. In conclusion, I would say that nowhere are slips and typographical errors more plentiful than in medical literature. For instance, in this very last number of the *New York Medical Journal* (August 29th, page 298) I find the following:

"Three such pills, coated with balsam of Peru, are to be taken every day." Now, pills never have been and never can be coated with balsam of Peru. What is meant is balsam of tolu (a solution of the latter in ether, which on evaporation leaves the pill with a smooth, impermeable coating, protecting it from oxidation, decomposition, or deliquescence). But in this shape it will probably go the rounds of the medical press, and I should not be surprised to see some physician prescribe those pills and demand, to the consternation of the druggist, that they be coated with balsam of Peru. This recalls to my mind a case which came to my notice about a year ago.

A young physician, just beginning practice, prescribed "tincture of chloride of zinc." The druggist said he could not fill the prescription, as there was no such thing. Being friendly with that physician, I asked him *entre nous* how he came to prescribe that tincture. "Why," said he, "Professor Morrow recommends it for spermatorrhœa." And indeed, on looking up my Morrow's *System*, I found that Professor Morrow did recommend potassium bromide in combination with the "tincture of chloride of zinc" in 15-drop doses (Morrow's *System*, vol. i, p. 1013).

To my mind there was no doubt that the tincture of chloride of iron was meant, but to a non-critical or not well-informed physician an error in a book or journal may be of serious consequences. Of this I could relate many instances, but, as my letter is already about five times longer than I had intended it to be, I will put a period to it.

WILLIAM J. ROBINSON, Ph. G., M. D.

[In Waring's *Manual of Practical Therapeutics*, fourth edition, Philadelphia, 1886 (the only edition that happens

to be at hand at this writing), on page 225, there certainly occurs this statement: "As a remedy for scabies in children, Dr. Monti, of Vienna, employed the balsam of copaiba in twenty-seven instances," etc. In a footnote, Waring refers to the *Practitioner* for October, 1871, page 238, where we find an abstract of Monti's article, which is credited to the *Wiener medizinische Presse*, 1871, No. 28, and there it is balsam of copaiba that is spoken of and its use is said to be "less expensive than the similar method of treatment in which Peruvian balsam is employed." On referring to the *Wiener medizinische Presse*, we find an abstract of Monti's article, which was originally published in the *Jahrbuch der Kinderheilkunde*, and in that abstract it is certainly balsam of copaiba that is treated of.]

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eighteenth Annual Congress, held in Pittsburgh, Pa., Thursday, Friday, and Saturday, May 14, 15, and 16, 1896.*

The President, Dr. WILLIAM H. DALY, of Pittsburgh, in the Chair.

(Continued from page 333.)

**Nasopharyngeal Fibroid Tumor.**—Dr. E. FLETCHER INGALLS, of Chicago, read a paper on this subject. (To be published.)

**Nasopharyngeal Fibromata.**—Dr. C. M. SHIELDS, of Richmond, Va., read a paper on this subject. (See page 354.)

Dr. W. E. CASSELBERRY said: One might think that with due observance of the technique described in these papers, it was a comparatively easy matter to remove these fibroid tumors, but it is not always so. If the tumor is broadly pedunculated and not bound down by adhesions the plan will succeed, but if, as in one case of my own, the tumor is firmly attached in all directions by firm adhesions, binding it on each side to the orifice of the Eustachian tube and firmly to the posterior pharyngeal wall, the tumor itself sending prolongations into the nares, it may be impossible to envelop it by a wire. After working for hours I succeeded in removing but a small piece, and this by first cutting places for the wire through the adhesions and into the substance of the tumor. The patient passed from my observation; relieved, but not cured. I think an external operation for access to the growth would have been justified in this case, or, at least, splitting of the velum palati, to enable one to detach the adhesions and then to envelop the growth. Of course, all external operating is to be avoided when it is possible, by ingenious technique, to remove the fibroid tumor *per vias naturales*.

I recollect a case recited by Dr. Lincoln, of New York, in which he succeeded by electrolysis, and I am desirous of giving this a thorough trial for fibroma of the nasopharynx. I noted that the second paper mentioned that the bipolar method of electrolysis was the most painful. This is not my experience with electrolysis when used for the reduction of spurs of the nasal septum. It would seem natural that the unipolar method would be most painful, for with a large part of

the body as resistance in the circuit a stronger current must be used.

Dr. A. W. DE ROALDES said: Dr. Casselberry's experience has been mine. It is not easy to remove a growth, for the reason he has given, and you will often find that extensive adhesions will prevent the encircling of the tumor. In one case I became aware of these adhesions by the fact of my non-success. Upon a closer inspection of the post-nasal space I found extensive adhesions that I could almost see. You will find that slitting the palate, which can be afterward sewed up, will help you considerably. As to the removal of a portion of the maxillary bone, it will facilitate the handling of the tumor. I also concur in Dr. Casselberry's remark concerning the bipolar method for the reasons he has given. The resistance is certainly less. Your electrical wedge passes between the two electrodes, and in one of the cases in which I employed this method the results were good.

Dr. J. E. H. NICHOLS said: I agree with Dr. de Roaldes. In one case in which I desired to ensnare one of these growths I found it impossible to do so. After several hours of work I finally succeeded in removing it with my finger nail. There was no hæmorrhage, and the patient made a good recovery.

Dr. INGALS said: In getting the snare about the tumor, we do not try to do it from the anterior nares. If the tumor has a large pedicle or broad it is necessary to use a hot wire.

Dr. SHIELDS said: I never thought the manipulation easy; but by persistent effort I have always succeeded. Even if it does require a long time it is better than subjecting your patient to the dangers of a preliminary operation. With regard to cutting the palate, it is my experience that this is unnecessary if you accustom your patient to the presence of your finger. I put my finger up behind the palate and stretch it thoroughly, so as to make the parts susceptible to manipulation. I have been surprised to find the amount of stretching that is possible, and in a fairly good patient you can put your finger almost anywhere in the post-nasal space. Even if the attachments of the tumor are great, if you insert your finger for a moment to place the loop well up around the base, then remove it, and immediately turn on the current, you can accomplish your object. The heated wire will usually be found to be sufficiently buried to retain its position without slipping.

(To be continued.)

## Book Notices.

### BOOKS, ETC., RECEIVED.

Lehrbuch der Haut- und Geschlechtskrankheiten für Aerzte und Studierende. Von Dr. Max Joseph, in Berlin. Zweiter Theil. Geschlechtskrankheiten. Zweite vermehrte Auflage. Mit 29 Abbildungen im Text und einer farbigen Tafel. Leipzig: Georg Thieme, 1896. Pp. viii+416.

The Physiology and Pathology of the Cerebral Circulation. An Experimental Research. By Leonard Hill. M. B., Hunterian Professor, Royal College of Surgeons, London, etc. London: J. & A. Churchill, 1896. Pp. xvi+208. [Price, \$4.20.]

A Manual of Clinical Diagnosis by Means of Microscopic and Chemical Methods. For Students, Hospital Physicians, and Practitioners. By Charles E. Simon, M. D., Late Assistant Resident Physician, Johns Hopkins Hospital, Baltimore. With One Hundred and Thirty-two Illustrations on Wood, and Ten Colored Plates. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xix-17 to 504. [Price, \$3.50.]

Minor Surgery and Bandaging, including the Treatment of Fractures and Dislocations, the Ligation of Arteries, Amputations, Excisions and Resections, Operations upon Nerves and Tendons, Tracheotomy, Intubation of the Larynx, etc. By Henry R. Wharton, M. D., Demonstrator of Surgery in the University of Pennsylvania, etc. Third Edition, thoroughly revised and enlarged, with Four Hundred and Seventy-five Illustrations. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xi-13 to 597. [Price, \$3.]

The Ready-Reference Handbook of Diseases of the Skin. By George Thomas Jackson, M. D., Professor of Dermatology in the Woman's Medical College of the New York Infirmary, etc. With Sixty-nine Illustrations. Second Edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. viii-13 to 594. [Price, \$2.75.]

Ptomaines, Leucomaines, Toxines, and Antitoxines, or the Chemical Factors in the Causation of Disease. By Victor C. Vaughan, Ph. D., M. D., Professor of Hygiene and Physiological Chemistry in the University of Michigan, etc., and Frederick G. Novy, Sc. D., M. D., Junior Professor of Hygiene and Physiological Chemistry in the University of Michigan. Third Edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xii-13 to 604. [Price, \$3.]

Rheumatism: its Nature, its Pathology, and its Successful Treatment. By T. J. MacLagan, M. D., Physician in Ordinary to their Royal Highnesses Prince and Princess Christian of Schleswig-Holstein. Second Edition. London: Adam and Charles Black, 1896. Pp. xiii-324.

Rheumatoid Arthritis: its Pathology, Morbid Anatomy, and Treatment. By Gilbert A. Bannatyne, M. D. Glas., M. R. C. P. Ed., Hon. Physician to the Royal United Hospital, etc. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent, & Co., Ltd., 1896. Pp. xii-173. [Price, 7s. 6d.]

Southall's Organic Materia Medica. Being a Handbook treating of some of the more important of the Animal and Vegetable Drugs made Use of in Medicine, including the Whole of those contained in the British Pharmacopœia. Designed for the Use of Teachers, Pharmaceutical and Medical Students, Chemists, Druggists, and Others. Fifth and Enlarged Edition by John Barclay, B. Sc. Lond., Sometime Lecturer on Materia Medica and Pharmacy in Mason College, Birmingham. London: J. & A. Churchill, 1896. Pp. xix+307. [Price, \$2.10.]

A Manual of Venereal Diseases. By James R. Hayden, M. D., Chief of Venereal Clinic at the College of Physicians and Surgeons (Columbia University), New York, etc. With Forty-seven Illustrations. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xi-13 to 267. [Price, \$1.50.]

A Short Course of Experiments in General Chemistry, with Notes on Qualitative Analysis. By Charles R. Sanger, A. M., Ph. D., Eliot Professor of Chemistry in Washington University.

The Nebraska State Medical Society. Twenty-eighth Annual Session, 1896.

Prize Essays on Leprosy. Newman, Ehlers, Impey. London: The New Sydenham Society, 1895. Pp. 7 to 227.

## New Inventions, etc.

### A NEW TRACHOMA FORCEPS.

By E. G. RUST, M. D.,  
CLEVELAND, OHIO.

THE advantages of other forceps are combined in this instrument; it is a modification of Dr. Knapp's forceps, possessing the valuable roller feature of his instrument and the ability of the Noyes forceps to get into the fornix and angles of the lids. It is easily cleaned.

and the lines of construction are such that the rollers never bind.

Messrs. Tiemann & Co. have made several for me in their usual efficient manner and they have answered their purpose admirably.

## Miscellany.

### A Patient's Account of the Paris Pasteur Institute.—

The lay view of medical matters is often interesting. It is so, we think, in the case of the following account of a patient's observation of the working of the Institut Pasteur, reprinted in the *Sun* from the *Pall Mall Gazette*:

The Institut Pasteur is a substantial and handsome building, standing in a large garden with stables, kennels, and lapinière in the rear. It occupies a freehold site in the Rue Dutot, a street off the Boulevard Vaugirard, in a district on the south side of the Seine, remote from the fashionable centre of Paris. One side of the main building is occupied by the private residence of Mme. Pasteur, the widow of the illustrious founder of the institute. On the other side are a magnificent scientific library and the laboratories where work chemists of all nationalities. It will be understood that these laboratories, where experimental work is carried on, are entirely distinct from the hospital section of the institut devoted to the "antirabique" treatment. In the former, as I understand, experiments in different stages are now in progress for the treatment of croup, cholera, snake bite, etc. The gardens surrounding the institute are pretty and well kept, and here the patients lounge about and take their ease until the doctors arrive and the day's treatment begins.

About a quarter to 11 the day's performance begins. The concierge, a good-looking, soldierlike fellow with Napoleonic mustache and imperial, has struggled into a semi-military uniform, and stands sentry at the door of the doctors' room, and the great hall is filled with an expectant crowd of all ranks and conditions

of men. There are seldom less than sixty to eighty patients under treatment. Every day some new ones put in an appearance; every day some, their treatment completed, go, with hearty handshakes and good wishes. On the wall of the great hall hang announcements that "The anti-rabic treatment is entirely gratuitous," "The institute is supported by voluntary contributions." Patients wishing to subscribe are referred to the secretary's office. Whether they contribute or not is a matter between their consciences and their pockets; no knowledge of the subject comes into the operating department, nor, if it did, would the impartiality of the treatment be affected.

There is no priority under "la piqure" but the priority of the newest patient. There is not now the mixture of nationalities at the Pasteur Institute that was observable a few years ago. Spain, Italy, and Russia have all their own institutes, and the weary pilgrimages from these lands are ended, but in rank and condition, age and sex, the variety is endless and amazing.

The noise in the hall is increasing; a group of good-looking peasant girls are flirting, as good-looking girls will, with a crowd of lads; the flirtation degenerates into a romp, and the racket gets rather pronounced, so that one looks anxiously toward Napoleon, but he is a good-natured fellow and beams benignantly on the giddy young things. Presently he gives a stentorian shout of "Les Nouveaux," and silence settles down. It is the signal for new patients who have not yet undergone treatment to pass into the salle d'inscription for particulars of their cases to be taken down in the register. The examination is searching, and results in the institute becoming possessed of most facts of your family history and of the dog's as well, so far as the latter are ascertainable. The interrogatories are, of course, in the first instance, directed toward ascertaining the bare facts of each case, in order to prescribe the course of treatment. Fifteen days is the minimum period, which in more serious cases is extended to eighteen or twenty-one days. The number and position of the bites and the length of time which has elapsed before the patient reaches the institute are all factors in determining the result. In very severe cases what is called the "intensive" method is resorted to, a treatment which is admittedly not without risks. The prescription of the course of treatment is entirely in the discretion of the surgeon, but the broad rule is that a bite in the leg is the least important, a bite in the hand is somewhat more serious, and most dangerous of all is a bite in the head or face. If the dog have bitten one through one's clothes, and if the clothes have or have not been torn thereby, are also points which have to be clearly stated. Much of the information taken down is, however, required for statistical purposes. Although the institute refuses no case in which there is any suspicion of rabies, it is careful to classify its cases, according to the weight of evidence, thus:

Class A—Includes cases in which the biting animal has been proved by experimental inoculation to have been rabid.

Class B—In which a veterinary certificate of rabies has been provided.

Class C—In which no inoculation or veterinary examination has been made, but in which there was strong reason to believe that rabies existed.

The great element of doubt exists in the last-named class, and it is not surprising to note that over a long period of years the smallest percentage of deaths, 0.33,

occur in Class C. A veterinary certificate is, as a general rule, good evidence.

After the new patients' cases have been duly entered, the surgeon passes into the operating room, and a stentorian shout of "Preparez-vous" brings the waiting crowd to attention. Cases are treated in batches, the new being first attended to, and the others going in according to the stage of inoculation they have reached. After the inoculation, patients whose wounds are unhealed pass to another room, where they are dressed.

Each day at least one rabbit dies, the body is laid on ice, and, as soon as possible, dissected and the spinal cord carefully removed and suspended in a glass bottle, the bottom of which is covered with a layer of caustic potash for the absorption of moisture. The bottle is labeled with the date and put away in a cupboard in a room kept at an even temperature, from which daylight is always excluded. Each spinal cord will supply material for about thirty inoculations. The fluid for inoculation is prepared by crushing a small piece of this dried cord with rather more than six times its bulk of sterilized veal broth. From one to three cubic centimetres (fifteen and a half to forty-six and a quarter drops) of the fluid are used for each inoculation. Patients are inoculated in the sides, which are first dabbed with a solution of perchloride of mercury, and on the first day of treatment they receive injections on both left and right side of virus that has undergone fourteen and thirteen days' drying. This mild preparation confers protection against the effect of the second day's inoculation, for which virus of the twelfth and eleventh days is employed. On the third day ninth and tenth days' virus is used. After the fifth day the inoculation is made on one side only. By that time the virus of the sixth day's exposure is reached. Every day's treatment up to the ninth day shows a progressive increase in the strength of the virus, each injection conferring immunity against the effects of the stronger one by which it will be followed. On the ninth day the patient receives an injection of the most virulent virus used, that of the third day's exposure, which is fully equal in activity to the bite of a rabid dog. After that a somewhat less active virus is employed until the fourteenth and fifteenth days of treatment, when virus of the fullest activity is again used.

This is the ordinary treatment. Under the "intensive method," the operations are in the beginning repeated twice daily, so that four days' strengths of virus are used each day, the result being that the more virulent preparations are reached in a hazardingly short space of time, so that the risk of the patient's constitution standing the strain is an appreciable one. This treatment is only resorted to in cases of great severity.

All rabies statistics are more or less unsatisfactory, and it is difficult to arrive at any very exact figures as to the proportion of deaths that occur in cases where no precautionary measures have been adopted. The truth probably is that of persons bitten by rabid dogs six out of ten escape without very ill effect. The odds of six to four in one's favor in the race between life and death are not heavy, and if the Pasteur treatment can, as its latest figures show, increase them to three hundred to one, I think the Pasteur system will be held to have proved its value.

The charge has been made against Professor Pasteur that "he has invented a new disease, the addition of paralytic symptoms to the old hydrophobia." There is nothing new in dumb rabies. It is the all but invariable form the disease takes with rabbits, while it is unusual

in dogs and human beings, who generally develop rabies or hydrophobia in the raging form. That the patients who succumbed under the intensive treatment should have shown paralytic symptoms is curious, but similar cases were recorded long before the Pasteur treatment was established.

It seems probable that these deaths were due primarily to want of proper care, especially in the avoidance of cold. The defect of the system at the Pasteur Institute is the total absence of any direction to the patients as to the rule of life to be observed while under treatment. The only point that is impressed upon them is that they should take frequent warm baths. And, from the mixed nature of the company, this recommendation is perhaps made as much in the interest of doctor as in that of patient. Nothing, however, is said, by way of warning, against catching cold, and it seems almost certain that where paralytic symptoms have set in they have been the direct result of a severe chill taken in the middle of the treatment. Doctors of all nationalities are unanimous in the opinion that the treatment causes no pain or inconvenience. I do not find, however, that any of the doctors have ever undergone it. While it is quite true that no permanent painful consequences result from "*la piqûre*," it is equally true that it causes at times a good deal of local pain and discomfort. Children, on the whole, bear it best, and get soonest hardened to it. I have seen two cases of boys who fainted dead away on the first inoculation, who by the third or fourth day were perfectly indifferent to the whole process, left off their games to go in the "*piqué*," and came out to resume them with grins on their faces. Persons of maturer years, especially men of full habit, occasionally suffer a good deal from inflamed and swollen sides, and poultices and hot baths are the only alleviations. A conviction of the unimportance of the symptoms makes the doctor serenely indifferent to the patient's sufferings, which are sometimes accentuated by needlessly rough handling. Apart from merely local affections, the only noticeable effect of the treatment seems to be a tendency, more or less pronounced in different individuals, to cramp in the limbs, a modified form, it is to be assumed, of the paralysis of dumb rabies. But these symptoms seldom last longer than two or three days.

**The Medical Society of the Missouri Valley.**—The ninth annual meeting will be held in Council Bluffs, on September 17th, under the presidency of Dr. Frederic S. Thomas, of Council Bluffs. The programme includes the following titles: Something About Instrumental Labor, by Dr. F. Damour, of Boileau, Missouri; A Case of Anterior Dislocation of the Head of the Radius, by Dr. G. W. Boot, of Hartley, Iowa; Operative Techniques in Appendicitis, by Dr. C. C. Allison, of Omaha; Skin Grafting: a New Method, by Dr. J. W. Kime, of Des Moines; A Case of Chronic Pharyngitis Simulating a Tumor, by Dr. F. W. Dean, of Council Bluffs; The Treatment of Burns of the Conjunctiva, by Dr. D. C. Bryant, of Omaha; Breech Presentations, by Dr. A. D. Wilkinson, of Lincoln, Nebraska; Two Cases—Gastrochaphy for Dilatation of the Stomach, and Prosis of the Transverse Colon; and A Successful Gastro-enterostomy with the Murphy Button, by Dr. J. E. Summers, Jr., of Omaha; The Treatment of Hydrothorax and Empyema, by Dr. J. M. Emmert, of Atlantic, Iowa; Congenital Dislocation of the Hip, by Dr. B. B. Davis, of Omaha; Retrograde Catheterism, by Dr. A. F. Jonas, of Omaha; Mental Dynamics and Psycho-therapeutics, by Dr. W.

B. Lawrence, of Red Oak, Iowa; An Instructive Case of Labial Cyst, by Dr. R. M. Stone, of Omaha; Typhoid Fever, by Dr. M. C. Christensen, of Council Bluffs; Remarks on Appendicitis, by Dr. F. W. Porterfield, of Atlantic, Iowa; Meningocele, with a Report of a Case, by Dr. J. P. Lord, of Omaha; Pulmonary Tuberculosis; its Etiology, by Dr. C. Engel, of Aspinwall, Iowa; A Case of Gunshot Wound of the Rectum, by Dr. V. L. Treyner, of Council Bluffs. Other papers will be read by Dr. J. B. Barstow, of Council Bluffs, and Dr. R. Hanna, of Red Oak, Iowa.

**The Hack Tuke Memorial.**—The great respect in which the late Dr. D. Hack Tuke was held, both in England and in America, has led to a generally expressed desire that his memory should be perpetuated in connection with the great work to which he devoted his life, viz., the amelioration of the condition of the insane and the advancement of neurological and psychological medicine. With the view of carrying out this object, a committee has been appointed to solicit subscription in the United States and Canada. The fund obtained will probably be used to found a library in connection with the British Medico-psychological Association, to which Dr. Tuke's personal library has already been given. The committee ventures to make an earnest appeal for subscriptions to carry out this worthy object. Subscriptions may be sent to Dr. Charles W. Pilgrim, Poughkeepsie, N. Y., Dr. Charles G. Hill, 317 North Charles Street, Baltimore, or Dr. Frank C. Hoyt, Clarinda, Iowa.

**A Correction.**—We are requested to make the following correction, on page 318, in Dr. de Schweinitz's article on Hog Cholera, which appeared in the issue of the *Journal* for September 5th:

**Guinea-pigs.**

No. 348, wt. 12 oz.,	check, received	$\frac{1}{10}$ c. c. swine-plague culture only.	
" 249, " 8 "	" " " "	" " " "	and 3 c. c. serum.
" 350, " 11 "	" " " "	" " " "	" 5 " "
" 351, " 9 "	" " " "	" " " "	" 6 " "
" 352, " 8 "	" " " "	" " " "	" 6 " "
" 353, " 8 "	" " " "	" " " "	" 12 " "

Page 318 should read, ninth line from the bottom, "the swine-plague serum protected from or cured swine plague only, the hog-cholera serum protected from or cured hog cholera only."

**The Physiological and Therapeutic Action of Eucaïne.**—The *Nouveaux remèdes* for August 24th states that Gaetano Vinci has undertaken some experimental researches in regard to the physiological action of eucaïne (*Therapeutische Wochenschrift*, 1896, No. 18), and the results show that its physiological action is identical with that of cocaine. It is distinguished from cocaine by its slight toxicity and by the fact that it provokes a slackening of the pulse and hyperæmia, instead of the acceleration of the pulse and the ischæmia which follow the employment of cocaine. Eucaïne, then, occupies an intermediate position between cocaine and the group of local anæsthetics called by Liebreich painful anæsthetics. It is ranked with the trepacocaine which was made the subject of investigation by Chadbourne some years ago. Finally, eucaïne exercises no influence on the condition of the pupils.

With regard to its therapeutic action, says the writer, in ophthalmology it is as persistent and as energetic as cocaine. Its instillation does not cause mydriasis or paresis of the muscles of accommodation, and, owing to this property, it is indicated always when it is necessary only to obtain anesthesia without concomitant is-

chæmia. If the inflammation is very pronounced, cocaine is preferable. Other advantages of eucaïne are that its solutions do not become decomposed, and they may even be kept for a long time; furthermore, they may be submitted to prolonged boiling without being decomposed. In dermatology eucaïne has shown itself to be a good analgetic. In affections of the throat and nose it has not only demonstrated its anæsthetic action, but its complete harmlessness. An important fact to be noted here, says the writer, is the entire absence of all disagreeable effects upon the heart.

Schleich has employed eucaïne in solutions for anæsthesia of the mucous membranes and for anæsthesia by infiltration, in order to make a comparison of its action with that of cocaine, and there is no doubt, says the writer, that eucaïne may completely replace cocaine when it is necessary to obtain anæsthesia of the mucous membranes. The superficial anæsthesia which is obtained in these cases is not less pronounced than with cocaine; in a solution of the same strength, the results are more favorable with eucaïne. He also has ascertained that eucaïne is destitute of any energetic ischæmic action, and he has never observed any toxic symptoms following its employment.

On the whole, the author concludes, says the writer, that eucaïne may completely and advantageously take the place of cocaine whenever anæsthesia is to be provoked by simple contact, such as painting the mucous membranes.

Kiesel has employed eucaïne with great success in extracting teeth, and he confirms the assertion of others in regard to the entire absence of an unfavorable influence upon the heart. The anæsthesia following its use persists for a longer time and extends over a larger surface than that provoked by cocaine. The aqueous solutions of eucaïne which are kept at ordinary temperatures remain limpid. According to the author, as much as thirty grains of eucaïne may be injected without danger to the subject; that is, twelve entire syringefuls of a fifteen-per-cent. solution may be injected without danger. Half this quantity is sufficient for the extraction of teeth, and the patient suffers no pain during the operation. However, it is not always wise to consider eucaïne as a completely inoffensive substance, and it should be carefully administered when given in the same quantity and the same strength as cocaine. The great stability of the eucaïne solutions is another advantage which this drug has over cocaine.

**An Obsolescent Variety of Cretinism.**—Under this heading the *British Medical Journal* for August 29th published the following communication from Dr. William Rushton Parker:

Cretinism is produced by lack of thyroid function in youth, and varies in proportion to the lack of function and to the degree of youth at which the lack occurs. One variety is embryological, due to thyroid non-development or partial development, and is analogous to any other malformations by deficiency, such as acardia, acephalism, anencephalism, absence or arrested development of testicles, ovaries, uterus, or any other organ.

A second variety is due to atrophy of the thyroid parenchyma, occurring occasionally after a serious illness in childhood, and analogous to the atrophy of the testicles after mumps.

A third variety is due to goitrous degeneration of the thyroid body. This third variety seems to be fast vanishing from this country, judging from its extreme rarity

among the many scores of cases brought before the British Medical Association at its recent annual meeting. Nor is this to be wondered at, seeing that goitrous cretinism is most likely to occur in the worst breeding grounds of goitre (namely, in valleys where the right conditions for goitre happen to exist), and which are sufficiently secluded and benighted to induce frequent intermarriage among goitrous families. Improved sanitation and the opening up of secluded valleys will exterminate this variety of cretinism.

Half a century has not yet elapsed since Dr. Hugh Norris described the endemic cretins of the little Somersetshire village of Chiselborough, lying in a small valley hemmed in on all sides but the west by hills over four hundred feet high, its temperature mild, its lower part damp and dirty, and its immediate neighborhood densely wooded with orchards. In this small village of five hundred and forty inhabitants he found: (a) Four goitrous idiots, two of either sex; (b) sixteen goitrous imbeciles, four male and twelve female, all unable to articulate intelligibly, all with very bad memories, and all except one unable to earn a living; (c) five goitrous deaf-mutes, all females; (d) two or three hundred goitrous villagers, with low intelligence and defective speech, the most goitrous being also epileptic.

The above creatures were stunted and thick-set, with large head, abundant coarse hair, low forehead, small sunken eyes, broad face with flat nose, large mouth with thick lips, and rickety limbs, the expression laughing or pained or vacant, the gait waddling. They were mostly weak, mild, and harmless, and, if mischievous, only so from irresponsible ignorance.

The females greatly predominated, as in goitre. There was imperfect sexual development, though some of the worst cases bore children. The semi-imbeciles transmitted their imbecility to some, not all, of their children. The cretins prevailed mostly in the lowest and poorest parts of the village, but were not absent from the highest and most airy parts, or even from the families of well-to-do farmers. Several green, stagnant pools existed in the place; the air was necessarily stagnant, and often reeking with rotten vegetation; young strangers became goitrous on settling there; intermarriage was unusually common, and many similar cases existed in an adjoining parish.

Dr. Hugh Norris, who still lives in the same neighborhood, tells me that one solitary cretin now survives of about fifty years of age, the march of civilization having apparently stamped out the disease.

**Mental Therapeutics.**—Dr. A. T. Schofield (*Lancet*, August 29, 1896) thus concludes an address on this subject:

I have already pointed out how completely the whole of this science is ignored. Its power is everywhere seen and felt—in out-patient departments, in the hospital ward, in the consulting room, and by the sick bed; but it is seldom spoken about, and still less often taught, though few are bold enough to deny the potent powers of mental therapeutics for good. If one turns from the physician's daily life to his library one still fails to find in any modern system of medicine the subject fairly and fully recognized. I have looked through many leading systems of medicine, but in no standard work can I find this subject fairly considered and discussed. A volume called *Suggestions in Therapeutics*, from Nancy, shows the use of the unconscious mind as a curative agent when under hypnotic suggestion; but we want far more than

this. Here and there great masters in medicine have admitted the enormous value of mental therapeutics, but the subject has not been followed up save for the sake of filthily lucre by quackery. It is the same in the teaching, clinical or otherwise, in the hospitals or class-rooms. Students listen with rapt attention to the powers of guaiacol, piperazine, phenocoll, and the whole round of well-advertised modern drugs; but how often is their attention directed, save in ridicule, to this mighty curative agent, that in its powers pretty well balances the whole Pharmacopœia—the mind? Does any practical medical man doubt these powers? Is he not aware of the ingredient faith, which, if added to his prescription, makes them often all powerful for good? Does he not practically know the value of strongly asserting that the medicine will produce such and such effects as a powerful means of securing them? Have not general practitioners often seen how much more efficacious the very same drugs have proved when prescribed in the physician's solemn consulting room than they were when connected with their own humbler environment and less august presence? If, then, this power is so well known, why, in the name of common sense, should it be pooh-poohed and ignored as it is? It has its laws of action, its limitations, its powers for good and for evil; would it not clearly help the medical student if these were indicated to him by his lawful teachers, instead of his gleaning them uncertainly from the undoubted successes of the large army of irregulars? There can be no doubt that, after all, a silent revolution is slowly taking place in the minds of medical men, and that our present textbooks on disease, content with merely prescribing endless selections and combinations of nauseous drugs, and dismissing any mental cure in a single line as unworthy of serious consideration, will soon be replaced by others containing views more worthy of the century at the close of which we live. For although these drugs are still administered, but few medical men now believe that they are the cause of the cure, for very gradually it is beginning to dawn upon us that most nervous diseases are easily and naturally treated by mental therapeutics, and that the still persistent efforts to cure them by the stomach are neither reliable nor rational. It ill becomes, therefore, the medical man, who recognizes in these cases that it is the mind that cures, to decry any form of faith cure, however little its process may be understood by him in detail. We have seen that the powers of the subconscious mind over the body are well-nigh immeasurable; and knowing, as we now do, that our old division into functional and organic diseases is merely the expression of our ignorance, and that all diseases, even hysterical, involve some organic disturbance, we are prepared to believe that faith cures, putting into operation such a powerful agent as the unconscious mind, or, if you prefer the formula, "the forces of Nature," are not necessarily limited to so-called functional diseases at all. Dr. Tuke's cure of warts by faith is well known, and, in spite of the imposture that has lately been exposed at Lourdes, there is great difficulty in believing that the cures effected there and elsewhere are limited to what we call functional diseases. It is perhaps the connection of mental therapeutics directly with faith-healing, Christian science-healing, and hypnotism, and indirectly with liquid electricities, billionth dilutions, and quack remedies of all sorts, that has so far deterred the profession from examining very closely its wonderful powers. This disgust is natural if we consider, for instance, one or two sentences from Mrs. Eddy's book on Chris-

*tian Science*. She says: "If the disease is consumption, begin your argument by taking up the leading point, showing that it is not inherited, and that inflammation, tubercles, hæmorrhage are but thoughts, beliefs, mental images before mortal minds, not the immortal mind. Drugs and cataplasms are shocking substitutes for the dignity and potency of mind." And again: "Ossification, or any abnormal condition of the bones, is the action of the mind as directly as insanity. Bones have no more substance than thoughts; what we call matter was primitively error in solution." Small wonder, in the face of such remarkable statements, if some turn with disgust from the whole subject. But we do maintain that it is largely our own fault if the science of mental therapeutics is thus parodied, for it includes no such vain metaphysical theories as we have quoted, nor any such surrender of will and personality as hypnotism requires, nor the revolting assumption of the miraculous that is seen in many faith-healing centres. On the contrary, the careful study of the subconscious mind and its connection with the body on one side and consciousness on the other delivers us both from unnecessary hypotheses and objectionable practices. When these laws have become the subject of serious study, and when the whole science is better understood and earnestly taught in the profession, the misuse and abuse of this great therapeutic agent by ignorant quacks will largely cease and the true curative agent of nearly all diseases will at last stand revealed.

**The Influence of the Testicles on the General Condition.**—In a valuable article entitled *The Question of Castration for Enlarged Prostate* (*Annals of Surgery*, September, 1896) Dr. A. T. Cabot, of Boston, says:

In December, 1894, I saw James W., a strong man of seventy-five years, who had been troubled for five years with considerable difficulty in connection with urination. At the time that I saw him the catheter was being used regularly, as he was unable to pass water without it. He was then suffering from an acute attack of inflammation. This subsided somewhat after rest in bed, but during his treatment the catheter touched a stone and an operation was decided upon.

On January 2, 1895, the stone was easily crushed and pumped out. The patient being in good condition at the end of this operation, the testes were removed. Previous to the operation the patient was for the most part clear mentally, but occasionally had slight confusion of ideas. He tore off the dressing after recovery from ether, and was in a distinctly bad mental condition the following day. From this time he continued in a mildly maniacal condition, which persisted through the month of January, and presented the typical form of confusional insanity, with occasional exacerbations when he was quite maniacal and noisy. For some days after the operation he had considerable pain and increased resistance over the right kidney.

During this time the wound in the scrotum healed kindly, and the prostate diminished considerably in size, making the passage of the catheter much easier than it had previously been. On February 14th he passed some water voluntarily. On February 19th he was as much confused as ever, his mind occupied with delusions and often much depressed, referring constantly in his talk to the loss of his testes and to his business troubles. It was now decided to try the effect of the injection of testiculin.

On February 28th, when he had been for eight days

receiving from thirty to forty minims daily, the record was made: "The injections are very painful and are hurting him much. His mental condition has changed decidedly since they were started. His friends, who do not know the character of the treatment, are much pleased with the change which they began to notice two days after the first injection. He is less restless, sleeps better, and worries less."

On March 6th we have the record: "For the past four days the testiculin has been omitted, and there is a decided change for the worse, his condition having become much as it was two weeks ago. March 16th, testiculin is being used every day. Mental condition constantly improving."

After this, the injections having been very painful, they were omitted, and the mental condition continued steadily to improve. He was able to use a silver catheter himself, and finally left the hospital March 30th.

I heard later from his physician, Dr. C. D. Sawin, of Charlestown, that Mr. W. did quite well, and went about with some degree of enjoyment and comfort. Some time toward the end of May, after a long ride in a carriage, he was again taken down with acute symptoms, with considerable pain referred both to the bladder and the region of the right kidney. This was accompanied by high fever and delirium; and he gradually failed and died.

Dr. Sawin was able to get a partial examination, and found the prostate about the size of a hen's egg. The third lobe was enlarged to the size of a pullet's egg, and projected upward and backward into the bladder. On its apex was a calcareous deposit firmly adherent. Posterior to this, extending forward in the body of the prostate, was a cavity with smooth walls, which contained about a teaspoonful of gravel. The bladder wall was thickened and injected, and showed on its surfaces a few hæmorrhagic spots. The kidneys were in a state of acute pyelonephritis, and the right was about one third larger than normal.

I know of no other instance in which testicular extracts have been used in such a case as this, but the immediate improvement which followed confirms the belief that the loss of the testicles had something to do with the mania, and suggests the importance of a further trial of these extracts in similar cases. Care was taken that neither the patient nor the friends should have any idea of what was being given or what results were expected, so that the possible effect of suggestion should be reduced to a minimum. This would seem to be a necessary precaution in any similar trial; for suggestion is a powerful therapeutic agent in such functional nervous disorders.

Besides these immediate and psychic disturbances there are other cases in which the operation has a very decided depressing effect on the general strength of the patient, leading to an amount of shock quite out of proportion to the extent of the mutilation.

In other cases, again, the patients have borne the operation well, the wounds have healed kindly, and still, at the end of a fortnight, or perhaps a little longer, they have gradually failed without any marked change in their symptoms and have died. If a case of this sort comes to autopsy, it usually reveals a condition of pyelonephritis, and the death is perhaps sufficiently explained thereby. It is, nevertheless, a striking and suggestive fact that these patients who have been carrying the load of partially disabled kidneys for a long time, after a slight operation, which heals kindly, gradually

succumb by progressive loss of strength without any evident increase of symptoms pointing to an aggravation of the renal condition.

This seems to indicate that, by the removal of the testes, the vital force of the patient has been in some way diminished, and thus, in a measure, the theory of Brown-Séquard finds support.

As a further evidence of the effect produced upon the nervous system by the removal of the testes, it has been noticed in a number of cases that the patients afterward suffer from uncomfortable flushes of heat, similar to those experienced by women at the time of the menopause. Also distinctly hysterical phenomena have been observed after castration. On the other hand, cases are reported in which conditions of nervous excitability existing before have been relieved by the operation.

**The Mississippi Valley Medical Association.**—The twenty-second annual meeting will be held in St. Paul, on September 15th, 16th, 17th, and 18th, under the presidency of Dr. H. O. Walker, of Detroit. Besides the president's address, the preliminary programme includes the following titles: An Address in Medicine, by Dr. Harold N. Moyer, of Chicago; An Address in Surgery, by Dr. Horace H. Grant, of Louisville; The Clinical Significance of the Child's Fontanelle, by Dr. I. A. Abt, of Chicago; Proprietary Prescriptions, by Dr. W. W. Allison, of Peoria, Illinois; A New Operation for Cleft Palate, by Dr. Truman W. Brophy, of Chicago; Some Rarer Forms of Keratitis, by Dr. Carl Barch, of St. Louis; The Results of Operation *per se* in Cases of Tubercle and Cancer, by Dr. A. C. Bernays, of St. Louis; Mastoid Diseases, their Medical and Surgical Treatment, by Dr. S. S. Bishop, of Chicago; Rupture of the Chorioid Coat, by Dr. J. H. Buckner, of Cincinnati; The Operative Treatment of Pterygium, by Dr. Eduard Boeckmann, of St. Paul; The Treatment of Some Inflammatory Diseases of the Gastro-intestinal Tract—Kola, by Dr. Gustavus Blech, of Detroit; A Report of a Case Illustrating the Value of Secondary Physical Signs in the Diagnosis of Cardiac Diseases, by Dr. R. H. Babcock, of Chicago; Rhinoscopic Examinations in General Practice, by Dr. E. M. Behrens, of Minneapolis; Irregularities in Delivery due to Short Umbilical Cord, by Dr. Guido Bell, of Indianapolis; Gastro-jejunostomy in Gastrectasis, by Dr. A. H. Cordier, of Kansas City; The Conventional Treatment of Heart Diseases *versus* Positive Treatment, by Dr. Ephraim Cutter, of New York; Tonsillotomy by Means of the Cautey Blade, by Dr. J. Homer Coulter, of Chicago; The Newer Remedies in Otology, and their Results, by Dr. G. I. Cullen, of Cincinnati; Infant Feeding—The Antidyscrasic Action of Cow's Milk, by Dr. M. F. Cupp, of Edinburgh, Indiana; Ether and Chloroform; their Comparative Merits as Agents for the Production of General Anæsthesia, by Dr. W. S. Caldwell, of Freeport, Illinois; Appendicitis; to Operate or not to Operate, by Dr. J. H. Dunn, of Minneapolis; Syphilis as an Ætiological Factor in the Production of Tabes Dorsalis, by Dr. C. Travis Drennan, of Hot Springs, Arkansas; Preventive Medicine, by Dr. J. O. DeCoursey, of Libory, Illinois; Certain Misconceptions regarding Cardiac Murmurs and their Significance, by Dr. Arthur R. Edwards, of Chicago; A New Method of Fastening the Broad Ligament in Alexander's Operation, by Dr. J. Frank, of Chicago; Cholecystotomy in America, with a Report of Four Cases, by Dr. Alex Hugh Ferguson, of Chicago; Pleuritic Effusions and their Treatment, by Dr. G. Futterer,

of Chicago; Rational Operations for the Cure of Retroversions and Flexions, by Dr. A. Goldspohn, of Chicago; A Demonstration of the Therapeutic Action of Antitoxines, by Dr. E. M. Houghton, of Detroit; Stipiculture, by Dr. Florence W. Hayes, of Terre Haute, Indiana; On the Importance of Physical Signs other than Murmur in the Diagnosis of Valvular Diseases of the Heart, by Dr. James B. Herrick, of Chicago; The Neural Factor in Clinical Medicine, by Dr. C. H. Hughes, of St. Louis; The Value of Medicinal Antipyretics in View of Newly Acquired Knowledge respecting the Nature of Acute Infectious Diseases, by Dr. Talbot Jones, of St. Paul; The Treatment of Syphilis, by Dr. J. T. Jelks, of Hot Springs, Arkansas; The Physiological Treatment of Typhoid Fever, by Dr. Elmer Lee, of Chicago; The Pathology and Treatment of Suppurative Salpingitis, by Dr. F. F. Wirt, of Cleveland; A Further Contribution to the Ocular Treatment of Epilepsy, by Dr. Casey A. Wood, of Chicago; and the Decadence of the General Practitioner and the Reign of the Specialist, by Dr. D. S. Maddox, of Marion,

Ohio. Other papers will be read by Dr. H. O. Pantzer, of Indianapolis, Dr. A. H. Meisenbach, Dr. I. N. Love, and Dr. Bransford Lewis, of St. Louis, Dr. R. C. Hefebower, of Cincinnati, Dr. Henry Hatch, of Quincy, Illinois, and Dr. Augustin H. Goelet, of New York.

**A Surplus of Nurses in California.**—Although this journal is not "devoted to the profession of nursing," we cheerfully print the following:

At a regular meeting of the San Diego Medical Society, held on August 7, 1896, a committee appointed to investigate the grievances of trained nurses coming to San Diego under promise of remuneration submitted the following preamble and resolutions, which upon the call of yeas and nays were unanimously adopted, viz.:

*Whereas*, A number of trained nurses from the training schools of Philadelphia and Baltimore have been induced to come to San Diego on the representation that they could find employment here that would pay them from twenty to twenty-five dollars a week; and

*Whereas*, on coming here they have not found such work or such wages, but have been obliged in some cases to procure money from their friends or relatives in the East so as to enable them to return home, therefore be it

*Resolved*, That we state for the information of such who may hereafter be likely to fall victims to such misrepresentation that the profession of nursing is now greatly overstocked and that at no time has any demand or have such opportunities existed for trained nurses as represented, and be it further

*Resolved*, That to prevent such nurses from being imposed upon we advise nurses to make specific arrangements with responsible persons before coming.

*Resolved*, That a copy of these resolutions be sent to Eastern periodicals devoted to the profession of nursing.

**The American Academy of Railway Surgeons.**—The third annual meeting will be held in Chicago, on September 23d, 24th, and 25th, under the presidency of Dr. John E. Owens, of Chicago. Besides the president's address, the programme includes the following papers: The Diseases of Railway Men caused by their Occupation, by Dr. J. F. Pritchard, of Manitowoc, Wisconsin; The Personal Equation among Trainmen, by Dr. Robert Tilley, of Chicago; Penetrating Wounds of the Eyeball, by Dr. G. A. Wall, of Topeka; Penetrating Wounds of the Eyeball, by Dr. T. J. Redelings, of Marinette, Wisconsin; Penetrating Wounds of the Eyeball, with Special Reference to Differential Diagnosis, by Dr. D. C. Bryant, of Omaha; The Remote Effects of Bone Trauma, by Dr. D. S. Fairchild, of Clinton, Iowa; The Medico-legal Aspects of Floating Kidney, by Dr. R. Harvey Reed, of Columbus, Ohio; Railway Surgery, by Dr. Jessie Hawes, of Greeley, Colorado; Emergency Surgical Practice, by Dr. C. K. Cole, of Helena, Montana; First Aid in Railway Emergencies, by Dr. James E. Pilcher, of Columbus, Ohio; Experimental Research into Shock in Abdominal Operations and Injuries, by Dr. George W. Crile, of Cleveland; Shock and Collapse, with Special Reference to Amputations, by Dr. Webb J. Kelly, of Galion, Ohio; The Delirium of Shock, by Dr. R. S. Harnden, of Waverly, N. Y.; Injuries of the Hands and Fingers, by Dr. John McLean, of Pullman, Illinois; An Experimental Study of Colles's and Pott's Fractures on the Cadaver, by Dr. A. D. Bevan, of Chicago; The Cause and Mechanical Treatment of Subluxation of the Knee Joint, by Dr. S. L. McCurdy, of Pittsburgh; Compound Comminuted Fractures at the Knee, with a Re-

port of a Case, by Dr. W. A. Ward, of Conneaut, Ohio; The Relation of Tuberculosis of the Knee to Injuries of the Knee Joint, by Dr. H. Reineking, of Sheboygan, Wisconsin; Fractures of the Femur, by Dr. E. M. Dooley, of Buffalo; Past and Present Obstacles to the Radical Cure of Hernia, by Dr. E. Wyllys Andrews, of Chicago; and The Treatment of Tramps and Trespassers, by Dr. H. J. Williams, of Macon, Georgia.

**The American Association of Obstetricians and Gynecologists.**—The ninth annual meeting will be held in Richmond, Virginia, on September 22d, 23d, and 24th, under the presidency of Dr. Joseph Price, of Philadelphia. The preliminary programme includes the following titles: The president's address—Principles and Progress in Gynecology; Vaginal Hysterectomy by the Clamp Method, by Dr. Sherwood Dunn, of Los Angeles, California; Further Experience with Appendicitis, by Dr. A. Vander Veer, of Albany; The Relation of Malignant Disease of the Annexa to Primary Invasion of the Uterus, by Dr. A. P. Clarke, of Cambridge, Massachusetts; The Treatment of Puerperal Septicæmia, by Dr. H. W. Longyear, of Detroit; The Treatment of Posterior Presentation of the Vertex, by Dr. E. P. Bernady, of Philadelphia; The Relation of Local Visceral Disorders to the Delusions and the Hallucinations of the Insane, by Dr. W. P. Manton, of Detroit; The Differential Diagnosis of Hemorrhage, Shock, and Sepsis, by Dr. Eugene Boise, of Grand Rapids, Michigan; Movable Kidney: Local and Remote Results, by Dr. A. H. Cordier, of Kansas City; The Pathology and Indications for Active Surgical Treatment in Contusions of the Abdomen, by Dr. W. G. Macdonald, of Albany; Some Cases of Insanity in Women, by Dr. George H. Rohé, of Baltimore; Shall Hysterectomy be performed in Inflammatory Diseases of the Appendages? by Dr. L. H. Dunning, of Indianapolis; Dynamic Ileus, with a Report of Cases, by Dr. J. W. Long, of Richmond, Virginia; The Faradaic Treatment of Uterine Inertia and Subinvolution, by Dr. Charles Stover, of Amsterdam, N. Y.; A Plea for Absorbable Ligatures, by Dr. H. E. Hayd, of Buffalo; The Treatment of the Stump, by Dr. J. F. Baldwin, of Columbus, Ohio; Limitations in the Teaching of Obstetrics and Gynecology as Determined by State Medical Examining Boards, by Dr. William Warren Potter, of Buffalo; The Philosophy of Drainage, the Treatment of the Pedicle in Hysterectomy or Hystero-myomectomy in the Abdominal Method, by Dr. George F. Hulbert, of St. Louis; The Removal of the Uterine Appendages for Epilepsy and Insanity, a Plea for its more General Adoption, by Dr. D. Tod Gilliam, of Columbus, Ohio; The Albuminuria of Pregnancy, by Dr. A. E. Eklund, of Stockholm, Sweden; Unnecessary and Unnatural Fixation of the Uterus, and its Results, by Dr. James F. W. Ross, of Toronto, Canada; Sarcoma of the Urethra, by Dr. Charles A. L. Reed, of Cincinnati; Appendicitis as a Complication in Suppurative Inflammation of the Uterine Appendages, by Dr. L. S. McMurry, of Louisville; Gunshot Wounds of the Abdomen with the New Gun, by Dr. J. D. Griffiths, of Kansas City; Tubo-ovarian Cysts, with a Report of Interesting Cases, by Dr. A. Goldspohn, of Chicago; Obstruction of the Bowels following Abdominal Section, by Dr. George S. Peck, of Youngstown, Ohio; and a Memorial of Dr. Hiram Corson, by Dr. Traill Green, of Easton, Pennsylvania. Other papers will be read by Dr. John M. Duff, of Pittsburgh, Dr. Rufus B. Hall, of Cincinnati, Dr. George Ben Johnston, of Richmond, Dr. Walter B. Chase, of Brooklyn, Mr. Lawson Tait, of Birmingham,

England, Dr. Walter B. Dorsett, of St. Louis, Dr. W. E. B. Davis, of Birmingham, Alabama, and Dr. E. Arnold Praeger, of Los Angeles, California.

**Acrocyanosis.**—According to M. Crocq, says a writer in the *Journal des praticiens* for August 22d, this clinical syndrome begins imperceptibly. The patient notices that his hands and feet are becoming of a violet color, which grows lighter toward the wrists and the dorsal surface of the feet. The palmar and plantar surfaces are not so blue, but rather reddish in tint. The backs of the hands and of the feet are cold and dry, while their palmar and plantar surfaces are covered with a profuse perspiration. Pressure causes a white spot which disappears slowly. Slight shooting pains are felt in the extremities.

M. Crocq has observed two cases of acrocyanosis in hysterical subjects. He distinguishes this affection from Raynaud's disease and from Charcot's blue edema, as the acrocyanosis is permanent. It gives rise to slight pains, it is not ordinarily accompanied by local syncope, it does not cause the appearance of blisters or gangrene, and it does not abolish sensibility. There is no edema, paralysis, paresis, or contraction. M. Crocq seems to think that acrocyanosis is an hysterical vasomotor symptom.

**Two Curious Cases of Lightningstroke.**—The *Deutsche Medizinische-Zeitung* for August 20th gives an abstract of an account of these cases, by Dr. Koepelli, published in the *Korrespondenzblatt für schweizer Aerzte*, 1896, No. 6. On the 6th of June, 1895, two boys, aged respectively ten and sixteen years, took refuge in a shed to escape an impending shower. A stroke of lightning set fire to the shed and killed a dog that was with the boys. The people of the place hastened to the boys' aid, and found the younger one lying on his face writhing with pain; the other boy was stretched on his back apparently lifeless, but he revived to some extent on being carried into the house. In an hour after the accident Dr. Koepelli found both boys fully conscious and complaining of great pain. The younger boy's skin was partly reddened and partly covered with blebs over the left arm, the left leg, the left side of the body, the whole of the back, the left cheek, and the left ear. Above and below the left costal arch there was a patch fifteen centimetres long and ten centimetres wide which was of a deep blackish-gray color and felt hard and leathery. In the older boy the injuries were found more on the right side, and consisted of a great number of deep punctiform lesions of the skin looking as if numerous shot had been removed. Both boys were in good general condition; there was no paralysis and the organs of special sense were intact. There were, therefore, no electrical nerve disturbances, there was only scorching; nevertheless, the prognosis seemed unfavorable, especially in the case of the younger boy, full two thirds of whose skin had been burned.

The treatment was by rest in bed, light liquid food, and warm-water applications. In the case of the older boy recovery was uninterrupted, and he was able to be out of bed by the fourteenth day. On the third day the younger boy had an attack of profound collapse, for which alcohol in unlimited amounts was ordered, together with a continuance of the warm applications. During the night the boy consumed a bottle of Malaga wine, and on the next day he was found distinctly better. The burned spots were severely painful. Gauze spread thick with vaseline was applied to them, over

that there were laid six or eight thicknesses of compress moistened with a one-per-cent. solution of salicylic acid, a protective covered them, and a broad bandage was put on over all. The dressing was renewed once or twice a day.

In fifteen days after the accident the necrotic skin of the large burned area on the left side could be removed *en masse*; the cutis together with the subcutaneous cellular tissue had been destroyed. The ulcer remaining was twenty centimetres broad and twenty-four centimetres long. It was cleansed daily with a one-per-cent. solution of corrosive sublimate and dressed with an ointment of zinc oxide covered with moist salicylic-acid wadding. After a few weeks skin-transplantation from a calf was resorted to to hasten the healing, and it was ten weeks from the time of the injury when recovery was complete.

**Ovarine and Ovarian Juice in the Treatment of Chlorosis.**—The *Presse médicale* for August 15th publishes a report of a recent meeting of the Congrès française de médecine interne at which M. Spillmann and M. Etienne presented a paper on this subject. They thought that the morbid symptoms which often preceded menstruation might be considered as the result of an intoxication which disappeared after this function was established. The frequency of menstrual troubles was well known.

If chlorosis, they said, was a disease of the ovaries, their functions were changed or abolished, and with the suppression of menstruation chlorosis appeared. And, on the other hand, a defective general condition interfered with and impeded recovery of the ovarian gland.

If, however, the ovarian internal secretion was restored to the organism in any way, it was possible, perhaps, to stop the intoxication, to influence the organism in general, and to afford a means of recovery of the local ovarian affection.

The authors had made use of three products: The fresh ovaries of the sheep, dried ovarian substance, and ovarian juice prepared by the Brown-Séquard-d'Arsonval method. These remedies had been given to six chlorotic subjects, with the results that after the first dose very sharp pains, especially in the abdominal region, had been felt; there had also been headache and vague muscular pains. In two of the patients the temperature had risen to 99.1° and 100.2° F., and the pulse increased from 76 to 100. In three of the patients the remote results had been distinctly favorable; the general condition had been rapidly improved, the pallor diminished, the number of white globules increased, and the strength restored. Menstruation, which had been suppressed for over three months, had returned in one case in fifteen days after the beginning of the treatment; in another case it had returned at the end of three months.

The authors concluded that, in the treatment of chlorosis, ovarine favored the elimination of the toxins, and introduced into the organism an antitoxic principle, and in this way it exerted a favorable action on the general condition, on the increase in the number of red globules, and on menstruation.

**A Compound of Argon and Water.**—M. Villar lately reported to the Académie des sciences (*Indépendance médicale*, August 19, 1896) that he had found that under certain experimental conditions difficult to maintain argon would form with water a definite compound, a crystallized hydrate.

## Original Communications.

PRIMARY AND SECONDARY  
PHARYNGEAL TUBERCULOSIS  
FROM A CLINICAL STANDPOINT.\*By WALTER F. CHAPPELL, M. D., M. R. C. S. ENG.,  
SURGEON TO THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

It is not my intention this evening to discuss the ætiology or pathology of the subject of this paper, but simply to present some clinical facts as they have appeared to me.

For some years past various observers have stated the belief that pharyngeal tuberculosis was occasionally primary. Isambert, in 1875, described different forms of this affection, some of which he thought must be primary. Fränkel, a year later, said that although unable to prove it he certainly believed that one of his cases was primary. Within the past three years, Dieulafoy, Lermoyez, and others have published the results of their investigations and expressed the opinion that, under certain conditions, a tuberculous manifestation resembling in appearance adenoid tissue may occur in the naso-pharynx and pharynx. This has been my experience, and I have the pleasure of presenting to this meeting the history of a patient, which, I think, proves definitely the possibility of a primary tubercular infection through the pharynx and nasopharynx.

I also present the history of two cases of secondary pharyngeal tuberculosis.

The water colors which I will pass around, and the clinical facts of the cases, show clearly the difference between a primary and a secondary infection.

CASE I.—J. W., a man, aged twenty-four years; came under my care in April, 1895, suffering from acute laryngeal tuberculosis in an advanced stage, and extensive pulmonary involvement. The disease progressed rapidly, and early in June the right posterior pharyngeal pillar began to thicken at its lower part, and the infiltration gradually increased until the soft palate, uvula, and left post-pharyngeal pillar were involved. The invasion of the soft palate proceeded from the right side. On the tenth day from the first apparent invasion of the pharynx numerous yellow spots appeared on the right post-pharyngeal pillar; and on the twelfth day the pharynx presented the appearance shown in Fig. 1. The mucous membrane had previously presented a pearly gray, tense appearance, but within forty-eight hours its yellow spots resembled those seen in a case of follicular amygdalitis. At first the spots had a thin covering of epithelium, but in a few hours this broke down and bright yellow, curdy secretions dotted the surface. These were readily brushed off, leaving extremely small openings plugged with the same curdy-looking secretion. The uvula had been very oedematous prior to the appearance of the yellow spots, but as soon as

they began to discharge the swelling subsided and gave the mucous membrane a wrinkled appearance. The minute spots of ulceration soon coalesced and poured out quantities of thick, tenacious secretion.

FIG. 1.—Secondary pharyngeal tuberculosis.

The disease then followed the usual course of acute cases, making deep, irregular excavations in the soft palate.

The patient died late in July, surviving about six weeks after the pharynx was attacked.

CASE II.—M. H., aged twenty-five years; came under my observation in June, 1895. He had a large tuberculous ulcer, extending from near the anterior commissure of the larynx upward over the left side of the cushion of the epiglottis, with considerable superficial infiltration of the arytenoid cartilages and epiglottis. He remained under treatment for about four months, and although placed under the most favorable climatic and hygienic surroundings, and receiving every approved method of treatment for this affection, nothing seemed to arrest the progress of the disease.

Four weeks before his death the lower part of the right lateral pharyngeal fold began to enlarge slowly and assumed a shiny appearance. This condition gradually spread upward behind the posterior pillar until the infiltration presented a smooth, tense, ridgelike appearance. The right posterior pillar then began to thicken, similarly to the lateral fold, and the infiltration spread to the soft palate, and eventually to the uvula. By this time small yellow spots appeared over the seat of the first infiltration. These gradually spread upward on the lateral fold and posterior pharyngeal pillar, and subsequently broke down, forming small disseminated ulcers, which coalesced and followed a course similar to that described in Case I.

The left posterior pillar did not become infected, all of the infiltration having been on the right side.

Death occurred within five months of my first seeing him.

CASE III.—Maggie A., aged nineteen years; came to my clinic at the hospital early in September, 1895, complaining of considerable post-nasal discharge, stoppage of the nose, and discharge from the right ear. An examination showed some acute swelling of the pharyngeal tonsil, with more or less mucous discharge. The pharynx, soft palate, uvula, and tonsils appeared healthy. Soothing applications were prescribed, and a few days later the post-nasal discharge had greatly diminished.

At several sittings, extending over a period of ten

\* Read before the Section in Laryngology of the New York Academy of Medicine, April 22, 1896.

days, the adenoid tissue in the pharynx was removed with forceps under ordinary antiseptic precautions.

About a week after the last tissue was removed the patient returned to the hospital complaining of having chills and some pain behind the palate. She looked ill and was of an ashy-gray appearance.

FIG. 2.—Primary pharyngeal tuberculosis.

A post-rhinoscopic examination revealed the mucous membrane in a semi-inflamed condition, irregular and puffy in appearance, and somewhat resembling adenoid growths. Several of these masses were removed, and were so firm and hard that it caused considerable comment. The patient felt relieved after this operation, and did not appear again for three weeks, when she returned, having considerable swelling of the cervical glands of two days' duration. The enlarged glands were very painful and tender on pressure, especially on the right side. The lateral folds of the pharynx, especially the right side, were enlarged, and appeared as thick, nodular ridges of about the size of an ordinary lead pencil, and passed upward behind the soft palate, and joined a number of similar nodular-looking masses in the nasopharynx.

The lateral pharyngeal folds are shown in Plate II, and resemble an accumulation of large granules or irregular masses, tender and hard to the touch, and of a deep bluish color. The same condition and appearance existed in the nasopharynx. The uvula at this time looked healthy, but the mucous membrane of the pharynx had a bluish appearance, though not infiltrated.

The patient looked and felt ill, and had a temperature of 101° F. A careful examination of the lungs revealed nothing of importance, and there were no other symptoms pointing to any pulmonary involvement. An unusual condition was recognized, and after considerable questioning tubercular infection was diagnosed.

The questions brought out the following history:

The patient had always enjoyed good health until the present illness. For some months prior to her first visit to the hospital she had been the sole attendant on a sister suffering from a somewhat acute form of pulmonary tuberculosis. She had taken no care to prevent herself from becoming infected, and when her sister died, in July, 1895, the patient moved into the bedroom occupied by her sister, and used the same bed clothing and other things belonging to her sister, without disinfecting them.

Examination of mucus from pharynx and nasopharynx showed it to contain tubercle bacilli. Several pieces of tissue were cut from the right lateral pharyngeal fold,

and also from the nasopharynx, and submitted to Dr. Jonathan Wright, the pathologist of the hospital, for examination.

I am indebted to Dr. Wright for his careful examination and interest in the case. He has supplied the slide I am able to show you, and the following report:

DR. WRIGHT'S REPORT.—The specimen received from Dr. Chappell was a piece of tissue about ten millimetres in its long diameter and five millimetres in its short.

Half of this was sent to Dr. W. H. Park, who inoculated two guinea-pigs with it. Dr. Park reports that one of the guinea-pigs died in twenty-one days of septicaemia, and showed, in addition to this, typical tubercle in the spleen and other organs, the tubercles containing bacilli.

Four months later, the second guinea pig, which had presented signs of disease, was killed, and found to be suffering from disseminated tuberculosis.

The other half of the specimen was put in absolute alcohol, then in alcohol and ether, and imbedded in celloidin. Sections examined under a low power show a lymphoid tissue crowded with tubercle, presenting the picture shown in the drawing (Plate III).

Examined with higher power, the characteristic structure of tubercle, with many giant cells, may be seen, the areas of coagulation necrosis being shown as light spots in the drawing.

Sections were stained for tubercle bacilli. A few were found in two or three sections out of about forty examined.

The bacilli were never more than one to a tubercle granulum, situated usually in the centre of it, and sometimes in a giant cell.

DIAGNOSIS.—Miliary tubercle of lymphoid tissue.

The subsequent history of the case proves the correctness of this diagnosis.

Injections of creosote and lactic acid, also curetting, were thoroughly employed, with little benefit to the right side, but the left pharyngeal fold was considerably improved. Most of the fringed processes on the latter side disappeared, and the cervical glands diminished considerably.

During the latter part of January the right tonsil and the right pillars of the fauces thickened, grew oedematous, and assumed a light blue color. This condition spread upward to the soft palate and downward to the right side of the tongue. A small papillary-looking mass also appeared about this time in the interarytenoid space.

Almost daily examinations of the lungs had been made, by myself and others, from the time the infection of the pharynx was recognized. It was not until over four months from this date that any pulmonary lesion was discovered. This was first noticed in the right apex, and three days later in the left apex.

As soon as the disease invaded the lung tissue the case became one of acute pharyngeal, laryngeal, and pulmonary tuberculosis. The soft palate and pillars on the right, which had previously been simply thickened and somewhat swollen, became very tense and of a deeper blue color. On the right anterior pillar, small, curdy-looking secretions appeared and spread on to the tonsil, and subsequently extremely small, shallow ulcers developed, much different in appearance, however, from those in the two cases I have just reported. The mucous glands on the posterior third of the tongue enlarged enormously, and hung over the epiglottis. These masses were

round, of a grayish-blue color, and resembled clusters of polypoid tissue.

The two specimens I pass around were taken from this region.

Lastly, the arytaenoid cartilages and the mucous glands in the posterior commissure became puffy, making respiration quite difficult. At no time were the ventricular bands, vocal cords, or any other parts of the larynx implicated.

The final stage was reached about the middle of March, when all the infiltrated tissue began to break down into small, superficial ulcers, as already described. The pulmonary disease had also progressed with remarkable activity, and the patient succumbed during the last week of March.

From her past history, M. A. evidently had some post-nasal catarrh for several years, with some enlargement of the pharyngeal tonsil. Although the removal of the latter was done with every antiseptic precaution, there was an early recurrence of tissue, which, from microscopic examination and clinical history, was undoubtedly tubercular in character. A number of tubercle bacilli were discovered in mucus taken from various parts of the nasal fossæ when the diagnosis was made, and undoubtedly they were inhaled while she was nursing her sister or occupying the room in which she had died.

The possibility that no infection would have occurred if the operation had not been done, is very interesting. The first appearance of an infection in the nasopharynx, and the subsequent descent along the lateral pharyngeal folds to the root of the tongue, and later into the larynx and lungs, point conclusively to the initial seat of the primary infection. The later invasion of the soft palate and uvula resembled in appearance and history cases of secondary pharyngeal infections.

The water colors and clinical histories of these cases show differences between a primary and a secondary infection. In the former there is a proliferation of tissue at the seat of invasion, and evidence of an inflammatory process, with considerable stasis in the local circulation. At no subsequent period did this tissue break down or go through the process of ulceration observed in other infiltrations which were secondary in character.

In all the secondary cases seen by me, the infection was in the form of a general infiltration of the mucous membrane, which soon progressed to ulceration and destruction of all infected tissue.

In the primary case the local evidences of an infection of the pharynx and nasopharynx preceded the sympathetic swelling of the cervical glands by about four days, thus following the rule of other primary infections, such as syphilis and cancer, in which we have an early implication of the glands in the neighborhood of the infection.

Furthermore, the cervical glands in the primary case swelled quickly, had considerable inflammation and infiltration, and were very painful and tender, all pointing to an acute infection from a part in the immediate neighborhood.

In my own secondary cases, and also in some others observed by me, the cervical glands were enlarged some time before any pharyngeal invasions. In one case this

was very noticeable. The deep cervical glands from the clavicle to the angle of the jaw on the right side gradually enlarged from below upward, and subsequently a few on the left side became affected. They were never very tender, nor did they show evidence of an acute infection; but eventually a pharyngeal deposit of tubercle appeared.

In studying the histories of reported cases of pharyngeal tuberculosis, several observers mention the presence of a fringe of small excrescences extending along the posterior pillars of the pharynx and into the nasopharynx. This condition corresponds so closely with the writer's primary case that it seems very presumable that they also were primary.

Another interesting clinical fact in both forms of the disease is, that the right side of the pharynx usually is the first to show the tuberculous invasion.

In all of my secondary cases the infiltration began first in the right pharyngeal fold, passed on to the right posterior pillar, and thence to the right side of the soft palate.

In my primary case the infection was much more severe on the right side, and spread up the right side of the pharynx to the soft palate and reached the tongue and larynx, seemingly, entirely through the right side.

Furthermore, in nearly every case reported fully by other writers, mention is made of the right side of the pharynx being more severely infected than the left. This is undoubtedly due to the difference in the arrangement and distribution of the lymphatics on the right from those on the left side of the neck.

## THE SEQUELÆ OF SYPHILIS AND THEIR TREATMENT. NASAL SEQUELÆ.\*

By CHARLES H. KNIGHT, M.D.

THE topic for discussion which has been assigned to me is the sequelæ or late manifestations of syphilis as met with in the nasal passages. My paper will therefore not enter upon the question of primary infection in this region or consider the possibility of so-called secondary lesions developing upon the Schneiderian membrane. Medical literature contains the record of many cases of chancre of the nose, and at the present day we believe that the mucous patch may appear on the nasal mucosa, although its occurrence here is very rare and has been denied. Late syphilis of the nose may simulate almost any other lesion, simple or malignant; its development is extremely insidious, and its ravages may be very extensive. For these reasons the study of specific phenomena, as exhibited in the nasal chambers, is peculiarly interesting, and their early recognition is of the utmost importance. To illustrate, let me briefly re-

\* Read before the American Laryngological Association at its eighteenth annual congress.

cite to you a personal experience, by no means a rare one—and doubtless each of you could furnish a counterpart from his own observation—but to me it was full of instruction and warning:

In the year 1890 a girl of fifteen was brought to the Manhattan Eye, Ear, and Throat Hospital for epiphora from stenosis of the nasal duct. The duct was found to be obstructed at its nasal orifice by an enormous enlargement of the right inferior turbinate body, which completely blocked up the nostril and was adherent to the septum. The mass, supposed to be a simple hyperplasia, was removed with the cold-wire snare. In two weeks it had resumed its original proportions, but was much more sensitive and vascular. Malignancy was suspected, but the microscope discovered nothing except hypertrophy of the lymphoid elements in the mucous membrane, which resembled, in all respects, lymphoid tissue as met with in the nasopharynx. Again it recurred after removal, and in about three weeks the microscopic report became quite different. Now the case was put down as one of small round-celled sarcoma. All the characteristics of sarcomatous tissue were clearly defined. The patient was referred to a general surgeon, who advised excision of the upper jaw. Ten days later the girl came to the clinic complaining of a sensitive swelling on her left shin, and over the crest of the tibia was found a semi-fluctuating tumor of the size of a hen's egg. She was at once put upon mercury and rapidly increasing doses of iodide of potassium. Within two weeks this node, and at the same time the nasal tumor, disappeared, and there has been no sign of either since. She was kept under treatment several months and has been seen at the clinic within a year. There can be no doubt, therefore, that the nasal tumor was a gummatous infiltration, yet the case narrowly escaped going on record as one of sarcoma brought by excision of the upper jaw. At the outset the patient, as well as her relatives, was closely questioned as to the possibility of specific taint. Her history, her social position, and her appearance were above suspicion. The ultimate result must be considered more fortunate than it is in many similar cases, no damage being done beyond complete absorption of the inferior turbinate body.

The foregoing is a fair example of the course and results of a syphilitic process limited to the soft parts, and of the difficulty in reaching a diagnosis. We meet with a still more serious array of symptoms and much more formidable consequences when the septal cartilage is attacked or the bony framework of the nose is involved. In the former case a patient presents himself with a symmetrical swelling of the partition between the nostrils well forward, usually pale in color, and insensitive, as compared with a perichondritis from traumatism. The surface is frequently irregular, eroded, or even ulcerated, and bleeds readily on irritation. The amount of discomfort attending the condition depends almost exclusively upon the degree of nasal stenosis and not upon the acuteness or intensity of the process itself. The result in such a case is almost inevitable—namely, perforation limited only by the extent of the primary infiltration. In some cases such an accident may be prevented by vigorous treatment, but they are rare, and probably include only those seen early and those in which the

gummatous perichondritis is rather circumscribed. It by no means follows that all cases of perforation of the cartilaginous septum should be regarded as syphilitic. On the contrary, a large percentage of them are traumatic; in other words, they are induced by the habit of picking the nose for the purpose of dislodging a mass of inspissated secretion, which is apt to accumulate at the apex of a septal spur or over an area of atrophied mucous membrane. Such perforations are often found in individuals who are entirely ignorant of their existence, and from whom a syphilitic element may be positively excluded. It may be said of syphilitic perforations that they tend to ulcerate at their margins and gradually invade the columna, the tip, and alæ of the nose, or progress backward and involve the bony septum. In this way a large part of the skeleton of the nose may be destroyed, but if the ulcerative process be confined to the cartilage and do not creep to the margin of the nostril, little or no external deformity may result. I have in mind a case in which the cartilage and the columna were lost, and yet no disfigurement followed except a slight flattening of the tip of the nose, the loss of the columna being noticeable only when the head was thrown backward. The most effective method of arresting these ulcerations is by daily applications of chromic acid or nitrate of silver, in solution of twenty grains to the ounce and upward, according to the extent and activity of the process. The formation of hard crusts, which are a source of irritation as well as of fœtor, may be prevented by the frequent use of a spray of abolone containing ten drops of eucalyptol to the ounce. Of course, suitable constitutional treatment must not be neglected.

In a certain proportion of cases the disease seems to be primarily located, not in the soft tissues, but in the cartilage or bone itself, and by the time the patient applies for relief the process of destruction has been practically completed. Almost all the bones which compose the walls of the nasal fossæ may be attacked by a necrotic process due to syphilis. A hideous degree of deformity may result from loss of the bony supports of the external nose and from distortion caused by cicatricial contraction. In dealing with cases of this kind we have to decide first when and how to remove necrosed bone, and finally how to remedy the resulting deformity. As to the time of interference, it may be said that it is not always good policy to wait until the sequestra have become completely detached. The process of spontaneous separation is notably slow in syphilitic necrosis, and should be expedited, when feasible, by surgical means, shortly after the active symptoms have been controlled by treatment. It is, of course, very desirable to preserve as much tissue as possible, hence the importance of having the patient fully under the influence of specific remedies for a considerable time before resorting to surgical interference. Otherwise, tissues which should be saved may be injured or destroyed. Not infrequently the diseased bone disintegrates and is expelled in the act of

blowing the nose. At times fragments may be found lying free in the nasal fossa, whence they may be extracted through the anterior nares; or if their size or irregular shape prevents their removal by that way they may be pushed back into the pharynx and withdrawn through the mouth. It sometimes happens that a sequestrum is so large that the nasal orifices will not permit its passage, or so hard that it can not be broken up and removed piecemeal. Under such circumstances we may have recourse to the operation described by Rouge in 1873. In this method the soft parts, including the external nose, are detached by an incision along the gingivo-labial furrow and a dissection carried upward close to the bone until the nares are freely exposed. If necessary, additional space may be gained by chipping off with bone forceps the osseous margins of the *introtus nasi*. My first opinion of Rouge's incision\* has been confirmed on several recent occasions—namely, that it is especially adapted to cases of syphilitic necrosis, in which the size and shape of the sequestrum preclude its removal by the natural passages without extreme pain to the patient and damage to the soft parts.

The diagnosis of necrosis is seldom difficult. The characteristic odor of syphilitic *ozæna* is conclusive, but if need be may be confirmed by the exploring probe. It is not always easy to determine precisely what and how many bones may be affected, especially in cases of long standing. The landmarks may be so effaced by inflammatory thickening and cicatricial contraction that the parts can hardly be identified. Bone exposed by ulceration can not always be readily differentiated from dead bone. Hence the importance of rapidly getting the patient under the influence of internal medication. The parts should be kept clean by means of detergent sprays or douches. The fœtor may be modified, but can not be wholly corrected while the dead bone is retained. Yet attempts at its removal, unless its position and extent can be clearly made out, are unwise so long as the sequestrum is quite immovable, or if it be located high up in the nasal chambers near the *os planum* or the cribriform plate. The blind use of the drill or the burr, especially in the ethmoid region, can not be too strongly condemned. Exuberant granulations often spring up from the margins or base of an ulcer, and one may be tempted to reduce them with caustics or a curette. At times this may be necessary, but a wise conservatism in the use of destructive agents is to be recommended. I have never seen a genuine polyp in a case of nasal syphilis, except in one giving a clear antecedent history of nasal polypi.

In considering the question of relieving nasal deformity resulting from syphilis it is not my purpose to take up the subject of plastic surgery, or to refer to all the ingenious devices by which nasal defects may be remedied. Quite extensive loss of the external nose may

be repaired after a fashion by flaps taken from the forehead, the cheeks, or other parts of the body. Very remarkable success in counterfeiting a natural nose has been attained by the use of celluloid and other materials. I wish only to recall to your attention a method of overcoming the deformity known as "saddle nose," which results from more or less destruction of the cartilaginous and bony supports of the nose. It is not only a source of mortification to its victim, but may debar him from society as well as from employment. The unfortunate is generally glad to try any measure which may make him more presentable and enable him to gain a livelihood. The method referred to was first suggested by Létievant, and consists of inserting beneath the depressed nose a supporting framework of metal. Aluminum was first used, and subsequently C. Martin,\* of Lyons, made an artificial bridge of platinum, with lateral arms, to be imbedded in the superior maxilla on either side (Fig. 1). The latter was introduced into this country by Dr. R. F. Weir † in 1892.

The length and shape of the bridge and of the arms must be adapted to each individual case. The one here shown was worn by a patient for seven months and was then replaced by a larger one. The bridge is put in place through a Rouge incision, already referred to. Although the operation is comparatively free from risk, it is oftentimes very tedious, since great care must be employed in determining the dimensions of the apparatus and in properly fixing the ends of the supporting arms in the maxilla. In spite of the utmost precautions, the bridge sometimes becomes distorted, or its upper end erodes the overlying skin. Both of these accidents happened in the patient whose photograph is shown, and the bridge had to be removed (Fig. 2). At first the result appeared to be perfect, but after a few weeks the bridge seemed to become twisted out of place, the skin over the dorsum of the nose began to grow red and sensitive, and the plate threatened to penetrate. To prevent this disaster the arms were divided with bone-cutting forceps and the plate was withdrawn through the nostril. Notwithstanding this procedure, the skin ulcerated, and in process of repair a

puckered cicatrix rather added to the patient's disfigurement. Moreover, the retraction of cicatricial bands within the nose so obstructed the passage that their re-

FIG. 2, a.—Before operation.

peated division with the cautery knife became necessary to give adequate breathing space. A month ago I inserted another bridge in this case, similar to the one here shown, and up to the present time there has been no unfavorable symptom. The first operation

FIG. 2, b.—Six weeks after the insertion of the bridge.

on this patient was performed six years after his infection with syphilis, of which the early symptoms were meagre, and for which he never had any treatment until he came to the hospital. His urgent desire for relief from his deformity led me to operate, as I now believe, prematurely. Since the failure of the first attempt he has had thorough and prolonged medication, and, in con-

sequence, is in so much better condition that a good result may be expected. We have had a number of cases at the Manhattan in which this operation was undertaken by Dr. Hopkins, Dr. Nichols, Dr. McKernon, and myself, but except in three or four the permanent results have not been fully satisfactory. Nevertheless, I am inclined to believe that the failures have been due to faults of technics and selection of an improper time for operating, especially as regards the date of infection, and should not detract from the merits of the method. Dr. McKernon has two patients who have been wearing the bridge nearly two years with perfect comfort and complete relief of deformity. Dr. Weir informs me that in his best case the patient has retained the splint four years, but he has had several which were less successful. He considers it a good operation for cases in which the septum is entirely destroyed and there is no obstacle to drainage. Dr. C. A. Powers, of Denver, writes me that all of his three cases behaved well so long as they were under his observation. One patient retained the bridge about eighteen months. She was a syphilitic and finally died of tuberculosis. Another was a very complicated case in which an ala had to be formed from the cheek. On about the tenth day the bridge slipped and had to be readjusted. Neither of these cases, therefore, can be considered thoroughly favorable for operation. The third case was lost sight of in four months, meanwhile the bridge having been worn without objection. Dr. John A. Wyeth has used a platinum bridge in three cases. In two of these an armless bridge, which will be referred to later, was inserted. In one case in which a Martin bridge was introduced "the deformity was very greatly relieved, the patient was much more comfortable, and went home comparatively happy." At the end of eight months it was displaced by a blow and had to be removed. Dr. Wyeth counts this case as only a "partial success," although, until receipt of the injury, the bridge was entirely satisfactory. A case of operation by Dr. Emil Heuel, to whose courtesy I am indebted for the particulars, is an example of remarkably extensive necrosis due to syphilis of twelve years' standing, as well as of primary failure and final success of the platinum bridge. The nasal bones, vomer, lower half of the left, and a portion of the right superior maxillary bones, the ethmoid, the right lacrymal bone, and the superior, middle, and inferior turbinated bones had all been destroyed. The left incisor, canine, and bicuspid teeth were missing, and both maxillary sinuses were exposed. Three years ago a platinum bridge was put in, but it had to be removed in about six months on account of the irritation it excited. This patient has been wearing a bridge, modified by Dr. Heuel, for the last two years and a half without annoyance, and the case is considered successful.

My experience with the platinum bridge leads me to insist upon three points: 1. In syphilitic cases the patient must have had a thorough course of treatment,

and a sufficient period must have elapsed since the disappearance of active symptoms—not less than three years. 2. The dissection of the soft parts must be so extensive as to obviate the possibility of tension at any point, and especially over the bridge of the nose where the upper end of the plate is to rest. 3. The metal bridge must be so molded and smoothed down at its edges as to preclude the danger of friction and pressure upon the soft parts, and the ends of the supporting arms must be deeply buried in the maxilla, as otherwise they are liable to be dragged out of position. The tendency to retraction and collapse of the nostril, observed in some cases, may be prevented by giving considerable width to the arms at their line of junction with the plate. The cost of the platinum bridge, as originally made, which is an item of some importance in the class of patients usually needing this kind of attention, may be considerably reduced by having it cut from a single piece of metal (Fig. 3). This idea, suggested by Dr. F. E. Hopkins \*

FIG. 3.—Hopkins's bridge.

first put in practice by him at the Manhattan, was found to be satisfactory. The bridge should be partially shaped beforehand and may be trimmed to suit the case at the time of operation. The after-

treatment of operative cases should be very simple, consisting merely of an application to the external nose of a piece of lint soaked in boric-acid solution. On the fourth day, and daily thereafter, a warm intranasal douche of a similar solution may be carefully used. No sutures are needed in replacing the lip, and no bandages or dressing which may exert pressure should be applied. The patient should be cautioned to avoid talking and laughing, and for a week should be restricted to semi-fluid diet. In other words, the parts should be kept at rest as far as possible until the process of repair is well advanced and the tissues have become accustomed in a degree to the presence of the foreign body.

In conclusion, let me refer briefly to a series of experiments with an "armless" bridge in a class of cases in which only partial destruction of the cartilage has resulted in moderate sinking in of the nose. In two of Dr. Wyeth's cases this form of bridge was inserted through a median incision over the dorsum of the nose. In one suppurative occurred and the plate had to be removed. In the other the external wound healed without suppuration and without scarring, and the bridge is still in place. It seemed to me it might be possible to put a simple plate of metal under the skin, a bed having been prepared for it by a dissection carried on through the nostril. Such was found to be the case, but the behavior of the plate was rather surprising.

The deformity was corrected, the foreign body excited no disturbance, but in a few weeks it became evident that the plate was cutting its way through the columna. It was removed, and one having numerous perforations was introduced, in the hope that the penetration of granulations would furnish a sort of anchorage for the metal. The latter pursued a similar course, although its weight was hardly appreciable. It is possible that better success will attend a further trial of this plan, provided some other material, such as celluloid or vulcanite be used, or the metallic plate be made much thicker, especially at its lower end. Permanent improvement in the contour of the nose ensued even in those cases in which the bridge was retained only a few weeks. The obvious advantages of this method are that it not only dispenses with an external wound, but substitutes for a long and troublesome operation, necessitated by the use of the Martin bridge, one of comparative simplicity, which may be performed in a subject of average fortitude under local anesthesia.

## A NASOPHARYNGEAL FIBROID TUMOR.\*

By E. FLETCHER INGALS, A. M., M. D.,  
CHICAGO.

ALTHOUGH many cases of nasopharyngeal fibrous tumors successfully treated have been reported by laryngologists, yet the records seem insufficient in many instances to prevent the general surgeon from removing the superior maxilla in order to extirpate growths that might be quite as well destroyed through the natural passages; therefore, even if there were no other reason than enlarging statistics, I feel justified in reporting another case. In this case a method which I have not formerly tried, and have not seen recommended for the ultimate destruction of these growths, has been attended by such satisfactory results that I wish to call the attention of this association to it, hoping that it may prove beneficial in some instances where the galvano-cautery or the knife could not well be employed.

The case was that of a boy, C. R., eleven years of age, who came to me in April, 1894. I learned that an undue fullness of the right cheek had been noticed when he was only four or five years of age, and during subsequent years he had had much trouble in breathing through the nose, with excessive discharge and loud respiration and snoring at night. For many months before consulting me he had been under the care of another laryngologist for the treatment of a nasopharyngeal growth. The patient was in general good health, his strength was fair, his appetite and digestion were normal, and his development was as good as that of most boys of his age. He had very little sense of smell, the voice had a nasal twang, and there was great difficulty in breathing through the nose. Upon examination I found the left nasal cavity half closed by deflection and exostosis of the septum; the right was completely occluded by a reddish growth at its posterior third, and there was a large red tumor

\* Read before the American Laryngological Association at its eighteenth annual congress.

in the nasopharynx, slightly nodular in form, and firm but elastic to the touch. The tumor upon removal was found to measure two inches by an inch and a half in length and width, and one inch in thickness. There was a small ulcer on the lower part of the tumor caused by previous treatment. The tonsils were slightly enlarged, and the pharynx was covered by tenacious mucus, which came down from the nasopharynx. Although the right cheek was abnormally full, inspection showed no indication of a tumor within it, but palpation revealed a slight thickening at the back part just beneath the zygomatic arch. I recommended an operation, but the parents decided to wait for some time, and I did not again see the boy for three months, at which time the growth had slightly enlarged, and the patient was having occasional transient pains in the jaw. The parts were anesthetized as thoroughly as could be done by cocaine injected by means of a hypodermic syringe with a long nozzle through both nares. The cocaine solution was also sprayed up behind the palate with an atomizer having a long bent tip. Two small English catheters were then passed through the right naris and brought out through the mouth, and through these the two ends of a platinum wire nearly three feet in length were passed, the loop remaining out at the mouth and the ends being brought out at the nostril. The catheters were then removed, and the loop of platinum wire was drawn up about the base of the tumor. The ends of the wire were then passed through the double tube of a galvano-cautery *écraseur* and made fast. The patient was told there would be considerable pain in removing the growth, but was asked to bear it as long as practicable, and told that as soon as he requested it the heat would be turned off. The platinum loop was now drawn tight, the current turned on, and kept for a second or two, until the pain caused the boy to ask that it be discontinued. He was allowed to rest for five or ten seconds; the current was then again turned on for one or two seconds, and again cut off and he allowed to rest as before. In this way we proceeded until the base of the tumor, about an inch in diameter, had been cut through. The tumor was then drawn out with forceps through the mouth. There was considerable hæmorrhage from the mucous membrane of the right naris due to abrasion of the surface by the electrode or to slight burning during the operation. This was checked by a strip of surgeon's lint packed into the naris from the nostril. This lint had been prepared by soaking it in a saturated solution of iodoform in ether, allowing it to dry, then dipping it in a saturated solution of boric acid in alcohol and drying. Two days later the packing was removed, and the patient was given a spray containing one third of a grain of thymol and four minims of the oil of cloves to the ounce of liquid alboline. A similar spray was continued throughout the subsequent treatment. The nasopharynx remained sore for some time, and no further operative measures were taken until the 28th of August, when a deep channel was burned through a portion of the growth that remained in the back part of the right naris. Six days later it was found that the breathing had been very much improved by this last cauterization. At this time I removed a small piece of the growth, about a centimetre in diameter, with the galvano-cautery snare. Nearly a month elapsed before any other cauterization was done; at that time and subsequently at intervals of from ten days to two weeks the remaining portion of the growth was cauterized four times; about six weeks later it was cauterized again, and again about a month later. One

month later, February, 1895, a final cauterization was made to a small bit of the growth which still remained in the back part of the right naris. By this cauterization the last vestiges of the tumor in the nasopharynx and nasal cavity were removed, and it did not return, though some irregularity remained in the nasopharynx as the result of cicatricial adhesions following the various cauterizations. The boy breathed freely through both sides, and had no inconvenience excepting from profuse secretion of mucus in the nasopharynx and posterior portion of the nasal cavity.

He was, however, beginning to be greatly annoyed by his schoolmates, who called him "Lumpy Jaw," on account of the swelling in the right cheek, due to enlargement of a portion of the tumor which had passed behind the palate bone and out beneath the zygomatic arch. This tumor, which could be readily felt, was nearly two centimetres in diameter and three centimetres in length. It passed downward and forward from a broad base, where it emerged from behind the palate bone.

A number of years ago I treated a similar case, in which I removed the growth from the nasopharynx and nasal cavity; but an offshoot into the cheek was operated on externally by the late Professor Gunn, who found great difficulty in checking the hæmorrhage, and was unable to entirely extirpate the growth; indeed, it would have been impossible to do it without removing the superior maxilla. Remembering former experience, I did not deem it wise to attempt to remove this mass with a knife. A very favorable experience in reducing the size and checking for many months the progress of the disease in two patients with malignant growths in the fauces by the submucous injection of lactic acid led me to try that agent in this case. On the 23d of April, 1895, I injected into the growth through the mouth fifteen minims of a twenty-five-per-cent. solution of lactic acid, to which had been added about fifteen per cent. of carbolic acid. When the patient reported about a week later, I found that the face had been very much swollen after the injection, so that he could not eat for two or three days, and he had been obliged to remain home from school. The inflammation and pain were so great that the injection was not repeated until about seven weeks afterward, when I employed a weaker solution. The boy was brave and patient, but still suffered much from the injection. About three weeks later, July 9, 1895, four or five minims of a four-per-cent. solution of cocaine were injected into the tumor, and this was followed by the injection of about twenty-five minims of a twenty-five-per-cent. aqueous solution of lactic acid, containing five per cent. of carbolic acid and twelve per cent. of glycerin.

Two weeks later it was noted that the lower portion of the fibrous growth was very much smaller, though the upper part still remained quite firm and was not much reduced. At this time fifteen minims of the same solution were again injected, and two weeks later the swelling of the cheek was very much diminished. About two thirds of the tumor seemed to have been destroyed by the last two injections. It was then about fifteen millimetres in its longest diameter. The injection was again repeated, and I did not see the patient subsequently for two months, when a similar injection was made. One month later, November 9, 1895, the tumor was again injected, and December 30th a similar injection was made.

I did not see the patient again until February 21, 1896. At this time the swelling of the cheek had nearly disappeared, and it was impossible to make out distinctly

any part of the growth, though an indurated mass about the size of a large pea could still be felt in the upper back part of the cheek where the growth had formerly been. It was probably partly cicatricial tissue, and partly the remains of the tumor. This was injected as at the preceding visits. I have not seen the patient since.

It is too early to report this case as absolutely cured, but a removal of fully ninety per cent. of the tumor by the injections of lactic acid convinces me that we at least have it in check, and that we shall be able to prevent its further progress by the same means. I believe that an agent so potent in the destruction of abnormal tissues must be of great value in the treatment of tumors so situated that they can not be removed by the galvanocautery or knife. In using the injections of lactic acid, it is important that the solution should not be too strong. It is well to begin with about fifteen per cent., and to increase the strength gradually to about thirty-five per cent., but never to go beyond a forty-per-cent. solution; a fifty-per-cent. solution will usually cause a slough. The acid alone in solution causes great pain, but, when combined with about five per cent. of carbolic acid, there is very little suffering. In order to prevent the immediate pain of the operation, it is important to inject a few minims of a weak solution of cocaine. I employ a four-per-cent. solution that also contains other ingredients that I believe render it more efficient, and at the same time prevent in great degree unpleasant constitutional effects. This solution is similar to one I obtained from a dentist, who injected it into the gums to prevent pain in extraction of teeth. I have used it for several years in anesthetizing the nasal cavities previous to operations, and since employing it I have obtained the constitutional effects of cocaine very much less frequently than formerly, and anæsthesia has been more rapidly produced. The solution contains atropine (a heart stimulant and local anæsthetic), a tenth of a grain; oil of cloves (also a local anæsthetic and antiseptic), three minims; carbolic acid (a local anæsthetic which appears by coagulation of albumin to prevent the absorption of cocaine), ten grains; and hydrochloride of cocaine, twenty grains to the ounce of distilled water. Whether or not this particular combination is better than others I do not pretend to say, but I am sure that it is much more satisfactory than a simple solution of cocaine. The anæsthesia is obtained more quickly and maintained longer and unpleasant constitutional effects are infinitely less frequent.

**Minnesota Coroner's Fees.**—Where the coroner on the same day makes two separate examinations of two different dead bodies, or holds an inquest on one body and makes an examination on the other, the supreme court of Minnesota holds, in *Kistler vs. Board of Commissioners of Hennepin County*, decided June 24, 1896, that, under section 5554, General Statutes 1894, he is not entitled to a fee of five dollars for each examination and each inquest, or to anything more than five dollars per day "for the time actually spent."—*Journal of the American Medical Association*.

## A CASE OF PERICHONDritis OF THE LARYNX FROM AN UNUSUAL CAUSE.\*

By H. S. BIRKETT, M. D.,

MONTREAL,  
PROFESSOR OF LARYNGOLOGY IN MCGILL UNIVERSITY;  
LARYNGOLOGIST TO THE MONTREAL GENERAL HOSPITAL.

In the month of May last I was kindly asked by Dr. Lafleur to see a patient, Mr. H. S., in consultation with him, in reference to a difficulty of swallowing and pain in the throat.

Mr. H. S. had consulted Dr. Lafleur a week previously on account of a specific urethritis, which he had already been suffering from for the past three weeks. During this period he had taken large doses of sandalwood oil, which had been prescribed for him by a chemist.

At the time of consultation he was suffering from urethral discharge, sweating preceded by chill and fever, pain in the left knee, ankle, and right shoulder joints, and a soreness of the left side of the throat, especially when swallowing either liquid or solid food; at the same time the voice was decidedly hoarse.

A few days later the right knee joint became painful, the affected joints being swollen and tender. No redness of the skin covering the joints, and no elevation of bodily temperature during the intervals of the chill. While the joints were affected the urethral discharge ceased. Examination of the urine showed it to be dark and of a muddy color, cloudy, and having a heavy precipitate; strongly acid; specific gravity, 1.028, containing no sugar; urea, nine grammes to the litre and a gramme of albumin to the litre. Microscopic examination showed blood and pus cells and blood casts. The urethral discharge was found upon examination to contain large numbers of gonococci.

*Examination of the Larynx.*—The mucous membrane over the left crico-arytenoid joint was swollen and oedematous. The aryepiglottic fold on that side was not swollen. The true vocal cords were white in color; the movements of the left one, that of adduction and abduction, were decidedly slower than those of the right; pressure over the affected joint outside was very painful; no grating felt on passive movement.

The voice was hoarse and more deeply pitched than normal.

The treatment consisted in the constant application of a Leiter's ice coil, which afforded the patient a great deal of relief.

In the course of a week the swelling of the left crico-arytenoid joint coincident with the decrease of the swelling of the other involved joints had entirely disappeared, the voice regained its normal tone, and the vocal cord lost its impaired movement.

The occurrence of an acute perichondritis during an attack of gonorrhœal rheumatism is, I believe, of sufficient rarity to warrant the placing of this case on record.

123 STANLEY STREET.

**Change of Address.**—Dr. C. Burton Conner, from Boston to No. 49 Plymouth Street, Brockton, Massachusetts.

\* Read before the American Laryngological Association at its eighteenth annual congress.

## MYCETOMA, THE FUNGUS FOOT OF INDIA.

BY BENJAMIN F. POPE, M.D.,

SURGEON, U. S. ARMY.

AND D. S. LAMB, M.D.,

ARMY MEDICAL MUSEUM.

BRUNO LARAS, aged twenty-seven years, of Mexican parentage, married, father of three children. No history of syphilis, but he had some enlargement of the trochanter lymphatics and post-cervical glands. Dr. Pope first saw him January 31, 1877; for eight years the patient had had some disease of the right foot which had become intolerable on account of the tenderness and constant pain. He was thin and worn, partly from suffering and partly from starvation, for he was very poor. His foot was much enlarged, measuring eleven inches and a half over the metatarsal-phalangeal joints, and was nearly four inches thick at the base of the little toe. The dorsal, plantar, and outer surfaces were covered by a sort of eruption beginning at one point as a small, well-defined, subcutaneous tubercle; at another as a more diffuse, somewhat resistant swelling, with a feeling of fluctuation. Over the points of recent invasion the skin was pale, smooth, elevated, with no sign of inflammation, and ordinarily not tender on pressure. Later on these elevations underwent a general degeneration; the cuticle exfoliated, the covering tissues generally thinned, the sac ruptured with the discharge of a bloody serum, and perhaps a drop of pus. From the more matured points there were forced out under pressure small white granules surrounded by a drop of glutinous material. These granules were quite firm, resisting considerable pressure, and much resembled rice grains or poppy seeds.

On the plantar surface the disease began as small dark-blue vesicles, containing effused blood, varying in size from that of a split pea to a No. 8 bird shot; the tubercle was not well defined, probably because of a deficiency of plastic effusion in the thick, hard plantar integument. The degenerative process was as already described. On opening these blood blisters on the dorsum or sole of the foot, the probe detected a small subcutaneous excavation and a sinus one to three inches long, leading upward, downward, or laterally toward the tarsal or metatarsal bones; but no involvement of the bones could be detected. The toes were as movable as the swelling would permit; no sound of rubbing or grating could be detected to indicate denuded bone. The mature points of eruption were dusky elevations of the skin, the summits of which were crowned with small knots of flabby granulation, from the centre of which there oozed, at times, a little bloody serum, and perhaps a drop of pus, hardly enough to stain the dressings. There was no induration of the bases of these elevations and no line of tegumentary demarcation; while the skin between the points was sometimes pale and greasy, at others dusky and glistening. Sometimes the sinus closed up after evacuation of its contents, leaving a small, irregularly depressed cicatrix showing a brownish centre and white border. The tissues surrounding the third, fourth, and fifth metatarsal bones, both on plantar and dorsal surfaces, were the most involved, and the disease did not extend beyond the metatarsus, except on the inner side of the foot, where there were one or two points of disease. The second and third toes were unaffected, except by edema, while the great toe was entirely free from disease. The general swelling

appeared to be due partly to edema, but mainly to induration of the tissues, and did not extend beyond the malleoli. The temperature of the foot was slightly elevated; pain constant, especially severe at night, and accompanied with aching in the joints. He went about with the help of a stick, and his constitution did not appear to be seriously affected. Appetite much better than his supply of food, strength fairly good.

*Diagnosis.*—Mycetoma or Madura foot of India.

*Treatment.*—A solution of sodium sulphite, twenty grains to the ounce of water, was injected into three sinuses, causing much pain, which subsided, however, in a few hours. A lotion of carbolic acid, five drachms to two pints of water, was given him for local application, and he was instructed to appear once a week.

*February 14th.*—Foot much swollen; less pain at night; the injected sinuses had closed; six others were now injected, forcing out granular bodies, with some blood and serum, not only from those injected, but others connected with them, the solution appearing at several points at the same time.

*21st.*—Sodium sulphite stopped because it caused too much irritation, and five minims of phenol, in one ounce of distilled water, used instead.

*March 1st.*—All the vesicles on the dorsum of the foot were opened and evacuated of their contents. The fistulae on the sole of the foot seemed deeper and more tortuous. The plantar cuticle in places looked as though it had been cut out with a punch.

*22d.*—Nocturnal pain had ceased; he could bear a little weight on the foot in walking; several sinuses on the dorsum had healed, but a fresh crop of tubercles had appeared in this situation. Each vesicle was incised at its summit, a grooved director inserted by its scoop end, and all accessible granules removed. Each opening was then injected with a twenty-minim solution of phenol to which twenty minims of solution of chloride of zinc were added. The injection caused much pain and much hemorrhage from the sinuses.

*May 22d.*—Admitted to post hospital, Fort Stockton, for operation, as there seemed no prospect of curing the disease. No permanent improvement could be recognized; there seemed to be just as many sinuses burrowing in the foot in all directions, and the disease seemed to be steadily approaching the ankle and diminishing the chance of a useful stump. The constant pain had shown its effect on his general condition.

*26th.*—Gave Squibb's ether, which he bore well, and Dr. Pope did a Girden's amputation, an inch and a half above the ankle joint. Long anterior and short posterior flap; anterior and posterior tibial arteries tied; about twelve other arteries and veins, which were much enlarged and surrounded by unelastic hardened connective tissue, were tied or compressed; the flaps were carefully examined and all suspicious points excised; they were then thoroughly bathed in a weak solution of carbolic acid, and after sufficient exposure to air were accurately sutured with fine silver wire; drainage openings below and on outer side; stump lightly dressed with old mosquito netting saturated with carbolic lotion, placed on a pillow, and surrounded by a cushion of finely picked oakum. There was no nausea or vomiting; the patient slept well after the operation; the next day he had no pain; there was moderate oozing from the wound. Union took place promptly; on the third day the unsutured edges were opened, and a carbolic horse-hair drain was inserted. Complete adhesion took place in less than ten days.

Examination of the amputated foot showed it distended with fatty tissue; there was fatty degeneration of ligaments, muscles, and connective tissue, including blood-vessels; these vessels seemed almost occluded by the pressure of the surrounding fat; the cancellous portion of the scaphoid and cuboid bones and bases and shafts of metatarsals were softened, friable, and excavated by atrophic process; there was no true caries; the outer surfaces were ulcerated and roughened by osseous deposits; the astragalus, os calcis, and lower ends of the tibia and fibula were normal. On removing the thickened plantar cuticle the sole of the foot looked as if it had been riddled with small shot at short range; sinuses and fistulae burrowed everywhere, communicating freely with each other, and ending in foci of granular matter mixed with grayish gelatinous exudate and some pus; the foci varied in size from that of a pea to that of a bullet and seemed not to be confined by any limiting membrane, but freely diffused through the degenerated tissue. There was no marked venous engorgement, but everywhere a distention and multiplication of cutaneous arterioles, probably compensating for the closure of the larger vessels. Many hæmorrhagic infarctions existed; the spaces were filled with grumous blood and communicated with the blood blisters.

The specimen, which was removed May 26, 1877, was received at the museum April 24, 1878. Was numbered 6,831, Pathological Series. Under date of March 8, 1878, Fort Stockton, Tex., Dr. Pope wrote: "The specimen of Madura foot is one of peculiar interest, as it is the only one I have knowledge of as occurring on this continent. Microscopic preparations of the peculiar fungus have been prepared rather roughly by me, but they exhibit very clearly the typical characteristics of the growth."

His microscopic examination is described as follows:

"The microscopic appearances of the different specimens submitted to inspection under a one-fourth objective of R. and J. Beck were somewhat conflicting and confusing. Thin sections from different portions of the degenerated tissues showed only the ordinary adipose cell, whose excessive proliferation was secondary to the original lesion and is common in all lipomatous tumors. Several of the poppy-seed granules taken fresh from their sinuses were without preparation submitted to sufficient pressure under a glass cover to permit the transmission of light, and showed what appeared to be irregularly shaped sacs, ruptured at different points, containing broods of ovoid non-nucleated cells (?). In granules treated with dilute acetic acid there was much the same appearance. Granules soaked in a solution of glycerin and distilled water, equal parts, for twenty-four hours, showed the sacs and all their intersecting spaces covered with a profuse hairlike growth, minute granules or spherules, fine threads, and complex rodlike and fimbriated cells. With oil of cloves this spore development was not so apparent.

"Before proceeding further, it becomes necessary for me to remark that it was only with the glycerin solution that the spores were seen at their best or even at all. Dilute acetic acid with glycerin seemed to check the spore development to a great extent. These facts led me to question the value of the appearance, for I was reminded that in other instances I had found the growth

of fungi peculiarly rapid and profuse in glycerin-water solutions; further, that this growth sometimes took place where there had been no apparent contact with organic germs, other than those that might have been absorbed from the atmosphere, and that the forms of these air growths were so numerous and so varied as to be wholly beyond my powers of classification or determination; so that what might or what might not have been an air germ developing under the glass cover of any ordinary microscopic specimen, mounted in glycerin solution, would be very difficult of decision.

"To insure, if possible, the entire exclusion of these foreign fungi, I took especial care in preparing a fresh solution of glycerin and water, and applying it directly to a fresh granule after it had been compressed under a thin covering glass, and then I sealed up all the edges with Canada balsam. An immediate inspection gave no result; after twenty-four hours, however, the spore development was well marked, and seemed to increase day by day for three days, when it ceased. In this instance even I am not prepared to say that the spores seen in connection with the specimen under examination were really a part of the diseased growth, though the probabilities seemed to be in favor of such a supposition; especially when one considers that the proliferation of the fungus was checked at the end of three days and did not spread beyond the borders of the morbid granule. Had it been an air germ developing under peculiarly favorable conditions one would suppose that the growth would fill the entire field of vision.

"Considerable difference will be noted between the East Indian and the American variety of the fungus, although the resulting lesions have a marked similarity to each other. The *Chionophye Carteri* has a large, spore-like cell, one one-hundred-and-twentieth of an inch in diameter, the fibres or threads of which they are the terminal expansions being one three-thousandth of an inch in diameter; these threads too are beaded.

"In the American variety perfect sacs containing brood cells are one five-hundredth of an inch in diameter; some are a third larger, made so, perhaps, by compression; while the hairlike mycelia are about one five-thousandth of an inch in diameter, three thousandths of an inch long, rarely more than this. They are tufted and bristling, often broken; they do not end in globular dilatations, but have free and rather wavy extremities, neither are they beaded. As before stated, there is minute granular matter in abundance, ovoid mononuclear daughter cells, one one-thousandth of an inch in long diameter, one five-thousandth of an inch in short diameter, irregular and rod-shaped cilia, complex fimbriated growths, that may be either true cells undergoing fissiparous multiplication, or mere accidental aggregations of brood cells."

*Note by Dr. Lamb.*—At the meeting of the Association of American Physicians and Surgeons, held May 30, 31, 1895, at the Army Medical Museum and Library, Washington, D. C. (see *Transactions of the society*, vol. x, 1895, pp. 92 *et seq.*), Professor J. George Adami, of McGill University, Montreal, Canada, reported a case of the ochroid form of mycetoma or fungous foot of India which had come under his observation, and stated that he did not know of any other case having occurred on this continent, although very likely such cases had occurred. Had I been present at the meeting I could

have told him that only a few yards from him—namely, in the museum hall—there was at that moment a specimen of mycetoma, received in 1878 from Dr. Pope, the story of which, however, had never been published. Some time afterward I wrote to Professor Adami and to Dr. Pope also in regard to the matter; in reply, Dr. Pope, December 16, 1895, wrote to me: "You are at liberty to publish such excerpts as you think proper, together with your own views, after examining the specimen."

The foregoing history of the case is substantially as reported by Dr. Pope. I have but little comment to make. The specimen and history together seem to me to show conclusively that the case is one of the ochroid form of mycetoma. It is probable that the patient had never been in India, and the museum specimens received from India accord with the observation that in India the dark form and not the ochroid is the one almost invariably found. The microscopical examinations made at the museum have been unsatisfactory, because the degeneration of tissues was too far advanced. The specimen has been freely opened and shows sinuses throughout, with brownish walls, and occupying the interval between the os calcis and toes; the bones in this space show more or less erosion, a rarefying osteitis; within many of these bony cavities, as well as in many of the sinuses, are still to be seen small roelike masses. The sole of the foot is well described above as looking as if it had been riddled with shot.

### THE DIAGNOSIS AND TREATMENT OF CEREBRAL MENINGEAL HEMORRHAGE.\*

By G. W. McCASKEY, A. M., M. D.,

PROFESSOR OF NERVOUS AND MENTAL DISEASES AND CLINICAL MEDICINE IN THE  
FORT WAYNE COLLEGE OF MEDICINE, FORT WAYNE, IND.,  
PRESIDENT OF THE NORTHERN TRI-STATE MEDICAL ASSOCIATION.

WITH the rapid and in some instances revolutionary changes which have occurred within recent years new questions are constantly confronting us and old ones require to be examined in a new light. Among these changes perhaps none are more noteworthy than the surgical invasion of the brain. And the circumstance that certain types of intracranial hemorrhage can be thus treated in a radically curative manner has given to the neurologist some difficult and often insoluble diagnostic problems. It is from the standpoint of the neurologist and general diagnostician that I shall consider the subject which forms the title of this essay, and which is of both neurological and surgical interest.

The anatomical relations of the cranio-cerebral structures are such that meningeal hemorrhage may occur either between the dura and skull, between the dura and subarachnoid, between the latter and the pia, or beneath the pia. We thus have four possible forms of meningeal hemorrhage: Extradural, subdural, subarach-

noidean, and subpial. The arachnoid, for the reason that it is little more than a thin movable diaphragm between the dura and pia, is of but relatively little importance as a partition between the possible sites of meningeal hemorrhage.

The main questions then, as it appears to me, and which I will endeavor briefly to review, are:

1. Have we in any individual case really to deal with intracranial hemorrhage? 2. Is it meningeal? 3. Is it extradural or subdural? 4. What shall the treatment be? Of course it must be frankly conceded at the outset that in a considerable proportion of cases we are not yet in position to give a satisfactory answer to all, or even to any of these questions. There is probably no class of cases in which the diagnostician is put, so to speak, more fully on his metal, and in which the faculty of close and accurate observation and power of logical analysis are more imperatively demanded. But with all this he must often arrive at "lame and impotent conclusions," because of the present status of physiological knowledge and the frequent absence or faultiness of clinical histories.

The first question, as to the existence or non-existence of intracranial hemorrhage, I shall simply formulate. The problems of diagnosis are utterly different according as we have to deal with traumatic or spontaneous cases. In the former case we have to differentiate from contusion, concussion, depressed fracture, and abscess; in the latter, principally from embolism and thrombosis in the rapid cases, with the addition of abscess and neoplastic formations in the slower. Of course some of the conditions mentioned, coexisting with the hemorrhage, may render the diagnosis of the latter equally impossible and futile.

Passing at once to the next question, we will inquire whether, intracranial hemorrhage having been assumed, we can decide whether it is meningeal or intracerebral. In many cases we can not. But we are, fortunately, not without significant data, both as regards the symptomatology and clinical history, which will aid us in the solution of this practically all-important question. In the first place it may be remarked in a general way that if it is traumatic it is probably meningeal or both; and if spontaneous, intracerebral. These propositions must be received, however, with considerable mental reservation, inasmuch as there are numerous exceptions. In traumatic cases the already classical lucid interval between injury and pressure symptoms, whether its duration be of minutes, hours, or days, is almost conclusive proof of meningeal hemorrhage. This interval would probably always be present, however brief, were it not for the submerged consciousness of complicating conditions, which too frequently passes unbroken into that of hemorrhagic pressure. Attention has been called to the subsequent rise of general body temperature in cases of hemorrhage, as a distinguishing point between this and concussion. If Hutchinson's observation, that the brain in cases of

\* Read before the Indiana State Medical Society, at Fort Wayne, Ind., May 29, 1896.

concussion is pale and bloodless, is correct, a depressed local temperature would be almost a necessary corollary. The study of the surface temperature of the skull, then, ought to aid in the diagnosis, a rise indicating hæmorrhage or contusion. I can not refrain from remarking in this connection that I am firmly convinced, after a somewhat extended series of observations of the surface temperature of the skull in cases of brain tumors, meningeal hæmorrhage, and other cerebral lesions, that this aid to diagnosis is entitled to fuller recognition than it is now receiving.

The occurrence of spasmodic movements upon one side, preceding unconsciousness, points to hæmorrhage beneath the arachnoidea, and possibly beneath the pia. On the other hand, complete or nearly complete hemiplegia, with slight or transitory coma, is in favor of intracerebral hæmorrhage; while the deepest comas, in which the hemiplegia, if present, may be masked to casual observation, are found in hæmorrhages of the meningeal or ventricular type. Inequality of the pupils, with the dilatation on the side of the lesion, is in favor of meningeal hæmorrhage. So is pain not otherwise explained.

A few cases have been reported in which slow sub-arachnoidean hæmorrhage, spreading out over the surface of the hemisphere, produced rhythmical spasmodic movements of the opposite limbs. This, by itself, would not, of course, establish the diagnosis; but, if followed later by hemiplegia and coma, no doubt should remain that the case was one of meningeal hæmorrhage. In line with this observation it may be said that in any case of intracranial hæmorrhage, in which the symptoms begin very gradually, and progressively advance with some regularity, and after hours or days reach the stage of complete hemiplegia and coma, the case is almost certainly one of meningeal hæmorrhage, whether traumatic or spontaneous.

It will thus be seen that we are in possession of data which enable us in many cases, in which the clinical history is available, to distinguish between meningeal and intracerebral hæmorrhage with as much certainty as can be attained in the case of lesions of any other inaccessible organ.

We will now pass to the third question: Can we distinguish between the different forms of meningeal hæmorrhage?

As already indicated, the distinction of chief importance is between those which are extradural and those which are between the dura and the cortex, ignoring the particular forms of the latter, although some recorded cases, and especially one by Starr, indicate the occasional clinical importance of the subpial form, its anatomical relations, like those of the extradural variety, limiting its extension, and causing the focal to predominate over the pressure symptoms.

The positive diagnosis between extradural and subdural hæmorrhage is in the majority of cases difficult, and in many impossible. The very slow development

of symptoms following trauma, with paralysis and coma later, point very strongly to extradural hæmorrhage. Jacobson, basing his conclusions on the study of about eighty cases, asserts that dilatation of the pupil on the side of the lesion is diagnostic of extradural hæmorrhage. This phenomenon, which, as Jacobson justly observes, should be designated Hutchinson's pupil, is produced by the extension of clot toward the base, causing pressure on the third nerve. It seems doubtful, however, if much importance can be attached to it as indicating upon which side of the dura the clot lies. This is fully illustrated by a recent case of which I made a neurological study for diagnostic purposes, at the request of Dr. W. H. Myers, who subsequently operated upon the patient. In this case a post-operative subdural clot produced marked dilatation of the pupil on the side of the lesion, contrary to Jacobson's contention. In another case, which I saw in consultation with Dr. A. B. Darby and J. E. Shoewalter, of Waterloo, Indiana, the pupils were perfectly symmetrical, though immobile, and rather small. Post-mortem examination showed a large subdural clot just behind the arm centre, the operative relief of which I had advised, and which the examination demonstrated could easily have been accomplished. After a careful study of numerous recorded cases, and in the light of my own observation, I feel justified in asserting that the only thing which can be safely predicated upon Hutchinson's pupil is that the pressure is affecting the base of the brain upon the corresponding side. It is, however, of the greatest value in this connection; and when occurring in the historical development of the clinical picture of a case of meningeal hæmorrhage, it furnishes an external sign of internal events that is at once graphic and important.

In concluding this necessarily brief discussion of diagnosis, one fact should be kept constantly in mind; it is, that the hæmorrhage is almost certainly not extradural unless there is well-marked hemiplegia; and further, as it seems to me, unless the hemiplegia or other focal symptoms predominate over the symptoms of general pressure.

It would aid immensely in the final solution of these questions if general practitioners, who almost invariably see these cases first, would make an accurate record of the development of symptoms, and especially those relating to the pupils, to motion, and to speech.

We are now ready to rapidly consider the line of treatment to be followed in such cases. This should be, in a word, if I may be permitted to use a somewhat antithetical phrase, a conservatively aggressive combination of expectant, medical, and surgical measures, so modified as to meet the exigencies of each particular case. Let us particularize a little.

As soon as possible after the occurrence of a meningeal hæmorrhage, whether traumatic or spontaneous, the patient should be placed in a quiet, well-ventilated, and softly lighted or darkened room. The favorable influ-

ence of gravity should be invoked by elevating the head of the bed, avoiding such an inclination as would place the patient in a constrained position, thus producing nervous irritability, with increased heart action, and harm rather than benefit. The head should be very moderately raised on a small, somewhat firm pillow, avoiding too great flexion of the neck with its obstruction to venous return. The scalp should be shaved and disinfected in every case. This is imperatively demanded alike for the purposes of accurate examination, subsequent clinical study, surface applications, and, when required, surgical interference. There should be no compromise on this hair question. The brain is sufficiently inaccessible, and its symptomatology sufficiently ill-defined without further obscuration by a cushion of hair.

Stimulants and heart tonics should not be given in any case of suspected meningeal hæmorrhage unless life is in imminent danger. Their indiscriminate use has often converted what might have been a trifling extravasation into one of fatal issue. The period of partial collapse is Nature's opportunity of sealing up the rent by a barrier which may be firm enough to resist the *vis a tergo* of a feeble heart, but which would give way readily before the throbbing currents of a heart goaded into violent action by alcohol, digitalis, or ammonia. On the contrary, the increasing force of the circulation should be carefully watched, and, when necessary, controlled by cardiac depressants. For the same reason the volume of the circulation should not be swollen by free libations of fluid.

The external application of cold is of the utmost importance. Surgeons have long been in the habit of controlling post-operative meningeal or even cortical hæmorrhage by the application of the ice-bag or a freezing mixture on the outside of the surgical dressing. These dressings are, of course, very poor conductors of heat, and it is perfectly obvious that the subcranial heat can be more rapidly abstracted through the better conducting media of shaved scalp and skull. The powerful hæmostatic action of cold, together with its sedative action upon the physiological processes of the brain, render it by far the most important non-surgical measure at our command for the purposes indicated.

These means having failed to arrest the hæmorrhage, the services of the surgeon should be requested in every case in which a localizing diagnosis can be made and the effusion is in an accessible location. Even when the localizing diagnosis is involved in some doubt, as it often will be, an exploratory operation should still be advised, if the gravity of the symptoms demand it. The neurologist may be unable to decide between two locations. The most probable one should be first operated, and if unsuccessful, a second opening unhesitatingly made at the alternative location. Such a case occurred in the practice of, I think, Dr. F. N. Dercum, of Philadelphia. The point at which he first directed the surgeon to operate was the wrong one. He advised a second, but the

surgeon declined to make it; post-mortem examination showed a meningeal blood clot at the second point indicated, and the patient would probably have been saved had the surgeon followed the advice of the neurologist. It probably requires considerable courage and confidence on the part of the surgeon to do this, in view of the uncertainties which frequently overhang the diagnosis of the neurologist in brain lesions, but the simple fact is that there does not seem to be, nor in the nature of things can there be, any better light to follow. Both neurologists and surgeons are learning the lesson that there is no special hazard in the removal of a few square inches of the cranial vault if done with proper precautions. There should be little hesitation, therefore, in giving to doubtful cases (properly selected, of course) the benefit of a procedure which will be diagnostic at least, and which may be radically curative.

While both the neurologist and surgeon should be progressive and bold enough to see their duty and to perform it, yet such measures must not be resorted to unless and until they are demanded either by the urgency of the symptoms or by the prospect of secondary changes which may imperil the patient's future.

When circumstances permit of continual watchfulness and prompt action at any time, the operation should not in many cases be performed at once, even though it appears probable that it will finally be required. Time should be given for the formation of a clot which will favor permanent closure of the vessel. Compression of the brain sufficient to produce mild focal symptoms will be tolerated several days without permanent damage. This gives ample time for watching developments and permitting spontaneous arrest. It must be borne in mind, however, that patients have gone to bed after very slight head injuries, with doubtful symptoms of meningeal hæmorrhage, gone quietly to sleep and wakened their companions in the night by the stertorous breathing of a coma which heralded impending dissolution. The watchfulness should therefore be unintermitting.

If the hæmorrhage ceases and the symptoms become retrogressive, but persist, should the skull still be opened? This must depend altogether upon the symptoms in each case. A reasonable time may be allowed for the complete disappearance of symptoms. If this does not occur, and especially if marked focal symptoms remain, and although all danger to life has apparently passed away, the operation should still be performed in order to save the patient from the results of chronic compression, with the symptoms of an irritative lesion, or possibly cerebral agensis, if the patient is sufficiently young. Such a result I recently saw in a case referred to me by Dr. George C. Stemen. The history indicated a meningeal hæmorrhage in childhood, and now at the age of eighteen or twenty years the patient is markedly hemiplegic and a confirmed epileptic, with the usual psychical tendencies. There are some things in this world that are worse than death, and this is one of them.

In conclusion, I wish to remark that while no one can be more painfully conscious than myself of the difficulties that are inherent in the diagnosis and treatment of meningeal hæmorrhage, yet I am fully convinced that there will be fewer fatal issues, fewer chronic hemiplegias, epileptics, and dementes, when we act fully up to the light which we now possess.

107 W. MAIN STREET.

## THE SEQUELÆ OF SYPHILIS OF THE LARYNX AND THEIR TREATMENT.\*

By WILLIAM K. SIMPSON, M.D.

IN presenting the discussion of The Sequelæ of Syphilis and their Treatment which has been assigned me, it is not my intention, nor will time permit, to consider the entire subject in detail, but simply to touch upon some of the more salient features, and to emphasize more particularly the treatment of the resulting chronic laryngeal stenosis by the method of intubation. The whole subject is a vast one and has been fully considered by others, but its importance and interest are such that one can always find profit in its consideration, even at the risk of repetition.

When we come to discuss the sequelæ of syphilis we are at once confronted with the importance of exactly defining the term *sequelæ*, and giving them their true relation in the progressive course of the disease. If we adhere to the older and more commonly accepted clinical division of syphilis into primary, secondary, and tertiary stages, then a consideration of the subject refers to that of the resulting conditions of a tertiary involvement.

The term *sequelæ*, as applied to syphilis, differs somewhat from its application to many other diseases; for example, suppurative otitis and chronic nephritis may become sequelæ of scarlet fever. Post-diphtheritic paralysis may be a sequel of diphtheria, and valvular disease of the heart of acute rheumatism, neither necessarily happening in the course of the disease, but as complications or accidents. With syphilis it is different; the late manifestations occur in regular order, and vary only in the length of time of their appearance and in their nature, as they may attack the various organs and regions of the body. Tertiary lesions are to be expected in due course of the disease, unless modified or stopped by efficient treatment in the earlier stages, and even this is denied by some.

I think, with a measure of correctness, that sequelæ of syphilis, as they pertain to the larynx, may occur (1) as acute exacerbations of long-standing tertiary conditions, and (2) the resulting permanent changes of tertiary lesions, both in their occurrence affecting the laryngeal functions of voice and breathing. These two

conditions are so often intermingled that we can not always make a perfect line of demarcation. Aside from these two extreme manifestations of syphilis, there are undoubtedly changes in the larynx other than of a purely structural nature, sufficient, at least, to interfere with phonation, and often of such a lasting and chronic character that the term *sequelæ* may be used. Under this division may be classed those patients who have syphilitic lesions in other portions of the body, while there have been no manifestations of a structural change in the larynx, the only involvement being a chronic hyperæmia, with attendant change of secretion, possibly some thickening, and the only subjective symptom being more or less hoarseness and loss of control of voice for any exactness of use. This is especially so in those who use their voices professionally, either in teaching, public speaking, or singing, or in the more violent use of the voice, which demands constant and regular shouting, seen in various occupations.

The overuse and strain of the voice, from whatever cause, unquestionably determines its functional impairment in many syphilitics, even if there is no direct specific lesion in the larynx. This impairment of the vocal function is also very prone to occur in chronic syphilitics whose occupations unduly expose them to inclement weather and climatic changes; this is especially seen among sailors. This passing involvement of the larynx may take place at any time during the course of syphilis, and must be taken into consideration whenever we are called upon to pass judgment on voice impairment. The treatment of this condition necessarily resolves itself into a judicious local treatment of the larynx, changes of environment, attention to hygiene, and regulation of the voice to meet the individual case, in conjunction with iodide of potassium and mercury, either singly or in combination.

Important as the above-enumerated causes may be in determining functional laryngeal impairment, wherein the larynx may not be, *per se*, the seat of syphilitic changes, much the more is their importance emphasized in those cases where the larynx has been, or is at the time actively involved, by a syphilitic lesion.

It is imperative that there should be a thorough appreciation of these sudden determining causes of exacerbation, as they are often the deciding point in diagnosis in cases of severity seen perhaps for the first time.

All serious intralaryngeal conditions in the adult, with a history of sudden onset, should at once arouse a strong suspicion of syphilis, and it may be said almost as a positive fact that all tertiary conditions of the larynx, of whatever nature and at whatever stage, are liable to sudden serious exacerbations. It is these sudden exacerbations, ingrafted on an existing lesion, that often produce the fatal occlusion, and by their acute swelling cover up and mask the underlying lesion. It is for this reason that when a case of laryngeal stenosis in the adult presents itself in the mirror as a smooth, uniform red

\* Read before the American Laryngological Association at its eighteenth annual congress.

swelling, we meet with difficulty, or fail entirely to relieve by intubation or other forms of dilatation; it may cover up a dense gumma, the dense swelling of a perichondritis, an irregular cicatricial contraction or deformity, or a subglottic stenosis.

Among the sequelæ of syphilis of the larynx, resulting from a previous active involvement, may be mentioned chronic thickening or induration, defined or diffuse; loss of tissue from ulceration, or from breaking down of a gumma, or from an abscess of a perichondritis; a deeper necrosis, affecting the cartilage, causing extrusion; ankylosed joints, paralysis, redundant and weblike tissue, and, finally, the resulting cicatrices, adhesions, and deformities.

It is not within the scope of my discussion to elaborate the different points of diagnosis of uncomplicated syphilitic lesions of the larynx, nor upon their differentiation from other lesions, and I will only say, in passing, that the isolation of the syphilitic preponderance is often a matter of great difficulty when there is an association with other dyscrasias, as, for instance, with rheumatism, tuberculosis, and malignancy. In one of my early reported cases of intubation in the adult there was a marked instance of the difficulty of distinction between rheumatism and syphilis of the larynx, the patient giving an ample history of both infections; the severer laryngeal conditions would yield only to the iodide in large doses, finally resulting in an ankylosis of the right crico-arytenoid joint; she subsequently developed a hemiplegia from a syphilitic brain lesion. The greatest difficulty of distinction undoubtedly exists when there is an association of laryngeal tuberculosis and syphilis, which combination, though rare, is, I think, generally admitted. We should be careful in committing ourselves to this coexistence in a given instance, unless tubercular bacilli can be found, either from pulmonary expectoration or from laryngeal secretion. G. C. Wilkin, of London,\* reports a case of pulmonary and laryngeal involvement pointing strongly to tuberculosis, both conditions, however, clearing up under the iodide. Several examinations for bacilli were made and they were not found, which fact, taken with the result of treatment, I think invalidates the theory of the combination of the two diseases.

I have at present under my care a patient with a long-standing syphilitic history who has developed a recurring, spindle-shaped sarcoma of the larynx, necessitating laryngectomy. The growth was removed in the first instance by the endolaryngeal method, and the patient placed on large doses of iodide of potassium. There was some reason for belief at first that benefit followed the use of the iodide, but at the expiration of nine months the growth recurred, and, in spite of the continued and increasing dosage, finally grew very rapidly.

The two great indications to meet in the treatment

of the more severe laryngeal sequelæ, aside from the arrest of the general progress of the disease, are the restoration of the voice and the resulting laryngeal stenosis. In short, we may say that all the sequelæ, other than permanent stenosis, must be met with the general principles of antisiphilitic treatment—namely, iodide of potassium and mercury, either alone or in combination. The condition of resulting stenosis must, in addition, receive mechanical means. It seems needless to refer to the efficacy of the time-honored use of the iodide in late syphilis, all of us knowing full well the brilliant results obtained; but there are undoubtedly certain instances where the combination of the two drugs is absolutely necessary, and some authorities maintain only the necessity of the mercurial treatment. This latter seems to be emphasized by the efficacy of the treatment of hereditary syphilis (which may be regarded as sequelæ) by the mercurial plan. In the *Revue hebdomadaire de laryngologie, d'otologie et de rhinologie* for February, 1896, M. Irsai gives a detailed account of the use and great benefit derived from the intramuscular injections of corrosive sublimate in severe forms of laryngeal syphilis, and relates a number of cases in substantiation. In the use of iodide it must be remembered that there occasionally happens in large dosage, and in susceptible patients, an aggravation of laryngeal symptoms. I have seen it determine redness of the larynx, dryness of secretion, and aphonia, where it has been given for syphilitic manifestations in other parts, principally in the pharynx.

The resulting chronic stenosis of the larynx, due to cicatricial contractions, distortions, indurated tissue, or whatever may be their nature, must be met by mechanical means in addition to the constitutional treatment. These two mechanical measures are tracheotomy and some form of dilatation or their combination. It is sometimes necessary to free weblike tissue and connecting bands before the latter measure can be thoroughly effected. Tracheotomy should be performed only where there is found to be an impassable barrier to the passage of the dilating instrument, or where the structure is of such a small calibre as to allow only of a very small breathing tube to be passed.

Before the introduction of the O'Dwyer method of intubation and the demonstration by it of the tolerance of the larynx to continued intralaryngeal pressure the treatment by the older methods of dilatation was extremely tedious and unsatisfactory. Intubation, by admitting of constant pressure, and at the same time allowing of free breathing while wearing the tube, overcomes this and gives us a rational method of treatment. The great objection to the Schroeter method, which is representative of the older means, was the necessity of a previous tracheotomy and the very transient and frequent introduction of the dilating instrument. The dense and unyielding nature of one class of stricture and the oft-times elasticity of cicatricial tissue are almost sure to recur immediately with anything but constant pres-

\* *Journal of Laryngology*, London, June, 1894; *Lancet*, London, June, 1894.

sure. There is unquestionably an absorptive process produced by constant pressure of the intubation tube in some conditions, while in other instances the constant wearing of the various-sized tubes produces an artificial canal through which the patient may breathe with much greater ease; it wears out in a great measure the recurring tendency, which has always been the great obstacle in the way of all previous measures. The increasing number of reported successes from all countries establishes, beyond doubt, the advantage of intubation in this class of cases, and of its general adoption.

It may be necessary in some cases to attempt some form of previous dilatation before the smallest-sized adult tube can be introduced, but these instances are rare, for if we are able to insert any instrument whatever, we can usually insert an intubation tube sufficient for breathing purposes. It is a well-demonstrated fact that one can breathe through an incredibly small space, provided it remains free and is constant in size. I saw a marked instance a short while ago in a patient whose pharynx and larynx had been reduced by cicatricial contraction to a small round aperture of about the size of an ordinary lead pencil, through which she both swallowed and breathed, and at the time I saw her there was but the slightest embarrassment with either function. Different portions of the larynx vary in their amenability to dilatation; the intracordal and subglottic spaces being the smallest regions of the larynx, and bounded by the restricting sides of the cricoid cartilage, allow of firmer pressure of the tube, while the supracordal region, being larger and more yielding, may necessitate the enlargement of the tube just below the head in order to exert better pressure at that point. The most difficult cases are those where intubation is resorted to in which a tracheotomy tube has been worn for a long while.

This arises from two causes: First, preventing the larynx from rising by its long inaction, so that in introducing the tube there is a greater distance to reach; and secondly, there is always an added stricture or a complete closure at the superior portion of the tracheotomy wound, which may require dilatation from below before the intubation tube may be successfully inserted.

Though the shape of the intubation tube for chronic stenosis to meet the average case is the same as those used for croup in children, being only larger for the adult, it may be necessary to modify both the shape and length to accommodate it for the given case in hand. It is also better to use the present form of probe-pointed tubes, as they enter a small stricture easier. It is necessary often to use considerable force in introducing the tube both to overcome the density of the stricture and any existing spasm. The length of time that a tube may be worn depends on the tolerance of the tube by the patient; this may vary from a day to several months. Metal tubes, as a rule, sink farther down in the larynx, and by their weight are generally better retained.

The act of deglutition while the tube is *in situ* be-

comes easier day by day. It may be necessary at first to have the patients swallow in the "Casselberry" position—*i. e.*, to swallow while on an inclined plane, head downward, or feeding in the beginning with a stomach tube. If possible, the tube should be introduced with the aid of a mirror in the same way as in making a laryngeal application, first cocaineizing the pharynx and larynx. After the point of the tube is seen to enter the stricture the mirror should be suddenly dropped and the forefinger of the mirror hand transferred to the head of the tube, making additional pressure while the introducer is being removed. It may be necessary in a long-standing case, in a tall patient, or where a tracheotomy tube has been worn, for an assistant to elevate the larynx externally; the mouth should be made as open as possible and the tongue well protruded. The string should remain in a few hours at least, at first, especially if the tube be of a small calibre, so that it may be easily withdrawn in the event of difficulty of breathing. In certain cases it may be necessary to etherize the patient, in which case the tube is inserted in the usual manner by the sense of touch. As a cautionary proceeding one should always be equipped to perform tracheotomy in the event of unsuccessful attempts at intubation in a serious case of obstruction. We must remember that cicatricial stenosis of the larynx is a serious condition in any event, fraught with many obstacles in the way of its relief, and any attempt toward its remedy must be tempered with a nicety of judgment and experience. And in conclusion, as far as intubation is concerned, I can not express my opinion as to its superiority over other measures better than by quoting the words of Dr. O'Dwyer, as I have done before—namely: "Had intubation of the larynx proved a complete failure in the treatment of croup, I should still feel amply repaid for the time and expense consumed in developing it, for I believe it offers the most rational and practical method yet devised for the dilatation of chronic stricture of the glottis."

952 LEXINGTON AVENUE.

#### NOTES OF

#### TWO CASES OF LOOSE BODIES IN THE KNEE.

By J. D. THOMAS, M. D.,

PROFESSOR OF GENITO-URINARY AND VENEREAL DISEASES  
IN WESTERN PENNSYLVANIA MEDICAL COLLEGE  
MEDICAL DEPARTMENT OF WESTERN UNIVERSITY;  
SURGEON AND GENITO-URINARY UROLOGIST, SOUTH-SIDE HOSPITAL,  
PITTSBURGH, PA.

The following cases of loose bodies in the knee joint have not heretofore been reported, and as they present some points of interest they may add something to the most instructive and interesting communication by Dr. Percy R. Bolton in the issue of the *Journal* of June 27th:

CASE I.—J. G., Irish, aged fifty years, was admitted to the South-side Hospital on March 19, 1895. On August 11, 1894, he was injured while working in a ditch. In some manner his left leg twisted under him and he

fell forward, striking upon his knee. This injury must have been quite severe, for he was removed to one of our hospitals, where he remained for some time (he does not remember how long), with a painful and swollen knee. He left this hospital before he fully recovered, and, after a period, although still lame, resumed work.

On October 24th of the same year, while working on a scaffold, about four feet from the ground, the scaffold fell and he again injured the same knee. From the receipt of the last injury until he entered the hospital, a period of nearly five months, his knee remained painful, and he was unable to do any work. By flexing the limb, and then suddenly extending it, he was able to demonstrate a moving body in the knee joint, on its inner side. On the next day he was anesthetized, the limb being already prepared, and an incision about two inches long was made over the joint below the inner margin of the patella. The extremity of the loose body was seized, and, on examination, it was found to be the posterior half of the internal semilunar cartilage, broken off at that part which is normally constricted, and loose excepting at its posterior extremity, where it was severed with the scissors.

The wound was closed by first uniting the incised synovial sac with a buried running suture of catgut, and the superficial incision with the same suture material. This was sealed with iodoform collodion, an antiseptic dressing applied, and the limb put up in plaster of Paris. At the end of ten days the dressings were removed, and the wound was found to be perfectly healed. In the meantime the temperature remained normal. The limb was kept in a plaster dressing for another ten days, and in less than a month the patient left the hospital.

CASE II.—S. B., negro, aged twenty-two years; admitted September 21, 1895. About three weeks ago, while running, he made a misstep and injured his left knee, since which time he has had pain in the knee joint, aggravated on attempting to walk. The circumference of the injured knee was half an inch more than that of the well knee. The synovial sac was distended with fluid sufficient to float the patella. On palpation, a loose body was detected on the inner side. The patient says the loose body has appeared since the injury. The limb was put up in a straight splint for a few days and iodine applied to the knee in order to reduce the more acute trouble. The steps of the operation in this case were identical with those in the first case. The body removed was ovoid, hard in the centre, as if an attempt at bony transformation was taking place, while around the periphery was a softer cartilaginous fringe. How much of an attachment, if any, this body had I am unable to state, for in making gentle traction in its removal it came away without any apparent resistance. The patient left the hospital in twenty-six days. The result in both cases was almost perfect.

These operations were performed without any difficulties, but no one should attempt an operation of the kind unless he understands thoroughly the technics, or, understanding it, is *sloppy* in its execution.

77 AND 79 SOUTH THIRTEENTH STREET.

**Dartmouth Medical College.**—Dr. William Thayer Smith, professor of physiology in Dartmouth Medical College, has been appointed dean of that institution to fill the vacancy caused by the death of Professor Carleton P. Frost. Professor Gilman D. Frost has been chosen secretary and treasurer.

## Therapeutical Notes.

**Valerianate of Creosote.**—Dr. E. Grawitz (*Therapeutische Monatshefte*, July, 1896; *Wiener klinische Rundschau*, August 23, 1896) has found this new preparation, which is a valerianic-acid ester of creosote, advantageous for the following reasons: 1. Being odorless and tasteless, it is readily taken. 2. Administered even in large doses, it seldom gives rise to digestive disturbances. 3. It is comparatively cheap. It comes in the form of gelatin capsules each containing about three grains. One capsule a day is enough to begin with, but the number may be increased until from six to nine are taken daily.

**Erysipelas of the Face.**—The *Presse médicale* for August 22d recommends the following formula:

℞ Carbolic acid,	
Tincture of iodine, { each . . . . .	30 grains;
Alcohol,	
Oil of turpentine . . . . .	60 "
Glycerin . . . . .	90 "

M.

The lesions are to be painted with this liniment every two hours, and covered with aseptic tarlatan.

**The Sweating of Phthisis.**—In the *Presse médicale* for August 22d we find the following formula for the sweating of phthisical patients:

℞ Sodium tellurate . . . . .	from 15 to 3 grains;
Alcohol . . . . .	750 "

M.

The dose is a teaspoonful every night and morning, in a little sweetened water.

**A Remedy for Obstinate Spasmodic Cough in Adults.**

—The *Revue internationale de médecine et de chirurgie* for August 25th attributes the following formula to Dr. J. B. Babcock:

℞ Bromoform . . . . .	113 grains;
Tincture of gelsemium sempervirens	120 "
Syrup of lactucarium . . . . .	975 "
Pulverized gum arabic . . . . .	q. s.

M.

From three to four teaspoonfuls a day may be taken.

**A Liniment for the Throat in Pharyngitis Sicca.**—

In the *Gazette hebdomadaire de médecine et de chirurgie* for August 20th we find the following formula:

℞ Glycerin . . . . .	450 grains;
Carbolic acid . . . . .	4 "
Tincture of aloes . . . . .	8 "
Tincture of iodine . . . . .	45 "
Wine of opium . . . . .	10 drops.

M.

**Antidiphtheritic Serum in the Treatment of Malignant Scarlatina.**—At a recent meeting of the Congrès français de médecine, a report of which appears in the *Gazette hebdomadaire de médecine et de chirurgie* for August 27th, M. Fournier stated that he had had occasion to use this serum in the case of a young child who showed an angina during the course of grave scarlet fever. The case was almost hopeless at the moment the treatment was begun, but from the first injection the coma into which the child had sunk disappeared and the subsequent injections led to a rapid recovery. Since then M. Fournier has employed this treatment in five similar cases, with the most successful results, and he recommends it in all grave cases of scarlatina.

THE  
NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, SEPTEMBER 19, 1896.

THE WOODEN PAVEMENT FROM A SANITARY  
POINT OF VIEW.

IN the *Lyon médical* for September 6th we find an important article on this subject by M. Rodet and M. Nicolas. They refer at first to analyses of old wooden paving-blocks made by M. Miquel, which they characterize as optimistic, and they conclude that the exceedingly favorable results arrived at by him are to be imputed to the fact that he examined the wood in a state of powder too coarse to show all the bacteria contained in it. They, on the other hand, subjected a fine powder to examination. Examining pine blocks that had been laid in Paris for several years, they found on the upper surface, after it had been washed, more than 50,000,000 microbes to the gramme (about fifteen grains); at a depth of a centimetre, 84,210; at a depth of three centimetres and a half, 43,100; and at a depth of five centimetres, 51,000. In a pine pavement taken up from a Lyons street in January, 1895, in foggy weather, after a number of frosts, that had been five years and a half in use and was highly impregnated with water, 79,360,000 microbes in the superficial portion, of which 96,000 were liquefactive; 489,600 at a depth of two centimetres, of which 1,600 were liquefactive; 116,800 at a depth of four centimetres, of which 400 were liquefactive; and 423,600 at a depth of six centimetres, of which 800 were liquefactive. In another pavement in the same street, taken up during a dry spell in March, 1895, they found at a depth of a centimetre and a half 2,361,600 microbes, of which 37,200 were liquefactive; at a depth of four centimetres, 250,800, of which 13,200 were liquefactive; at a depth of six centimetres, 63,600, of which 1,200 were liquefactive; and at a depth of eight centimetres, 110,400, of which 8,400 were liquefactive.

It follows that wet wooden paving blocks contain many more microbes than dry ones, and that it is especially in dry weather that the old pavements give off their microbes. In no instance did the authors find the *Bacillus coli* in the deep part of the pavement. Moreover, the micro-organisms found in the blocks proved almost innocuous when inoculated upon guinea-pigs. No more infective did the scrapings from the lower surface of the blocks prove. Nevertheless, the au-

thors consider their findings to be somewhat unfavorable to the use of wooden blocks for paving. The superficial portions of them, those that are most likely to give up their contents to the surrounding air, are abundantly impregnated with microbes, and they persist after the most careful washing.

SPLENIC EXTRACT IN THE TREATMENT OF  
CHLOROSIS.

IN the German market there is an extract of the ox's spleen known by the name of erythrol, which was first recommended as a therapeutical agent by Dr. Wilhelm Cohnstein. Dr. Max David, of Berlin, has had some experience in the use of it, and he relates it in the *Deutsche Medicinal-Zeitung* for August 27th. He has used it in two forms—that of fifteen-grain tablets coated with chocolate and that of the pure extract resembling Liebig's extract of beef in color and consistence. Dr. David premises that when he began to use these preparations in his practice he was prejudiced against them as he was against the many other proprietary panaceas, and he resolved to try them only in cases in which various preparations of iron, creosote, and the like had been resorted to with little or no effect.

He gives brief notes of six cases in which he has prescribed erythrol. The patients were four young women, a married woman, and a child ten years old. All the young women had dysmenorrhœa as an accompaniment of chlorosis. The extract was given in daily amounts of from half a teaspoonful to a teaspoonful, or the tablets were employed to the number of from two to three daily. The four young girls were much improved in the course of three or four weeks, if not cured, but the married woman and the child were not benefited.

The remedy proved to be of unexpected efficiency in overcoming dysmenorrhœa and in improving the appetite. The author admits that the number of his cases is too small to warrant his drawing general conclusions from them, but suggests that so far as they go they deserve consideration.

THE TOXINE TREATMENT OF MALIGNANT TUMORS.

IN the *Wiener medizinische Blätter* for August 27th we find an abstract of an account by Dr. Matagne, of Brussels, of his experience in the treatment of "inoperable" malignant tumors with Dr. Coley's erysipelas and *Bacillus prodigiosus* toxins, originally published in the *Gazette médicale de Liège*. He has employed the treatment in fourteen cases, and maintains that in one of

them a complete cure was accomplished. The patient was a man, sixty-four years old, who in January, 1895, first noticed something abnormal in his mouth. In February he consulted a physician, who diagnosed epithelioma and advised an operation, to which the patient did not consent. Many other physicians saw the patient, and they all concurred as to the diagnosis and urged the man to have an operation performed. Early in June the patient consulted Dr. Matagne. By this time he had a three-lobed tumor which occupied the floor of the mouth. The largest lobe was as large as a nut; in the left submaxillary region there was a gland as large as a small nut—the kind of nut is not specified in either instance—and under the chin there were two other glands of the size of a bean. The tumor was hard and ulcerating, but without suppuration, and lancinating pains proceeded from it toward the left ear. In a short time the symptoms were so marked that no observer had a doubt of the epitheliomatous nature of the growth. However, no histological examination of the neoplasm was made, for fear of opening a channel for secondary infection.

The treatment was begun on the 10th of June. Five centigrammes of the toxine were injected beneath the skin of the neck below the hyoid bone. In two hours the man's temperature was 101.3° F. On the 16th of June forty centigrammes were injected into the tumor, and hard swellings made their appearance in half an hour; the tongue remained quite swollen for two entire days. The highest temperature reached during the treatment was 105.8° F. During the whole febrile period the tumor diminished in size very decidedly, and the diminution kept on after the subsidence of the fever, so that by the beginning of September not a trace of the growth remained.

Another case was one of recurrent sarcoma of the neck in a woman seventy-eight years old. The tumor was as large as an egg and situated in front of the sterno-cleido-mastoid muscle. Another tumor, of the size of a hazelnut, was seated in the masseteric region, and two small but very hard glands were to be felt under the chin. After a course of treatment lasting three months and a half, the injections being given every second day, the large tumor had wholly disappeared and the one in the masseteric region could hardly be felt, but the enlarged glands had not undergone complete involution, when the treatment was accidentally interrupted. In six months after their discontinuance there was a moderate aggravation of the disease, and the patient was advised to submit to the injections again.

In a third case, one of recurrent sarcoma of the neck of the size of a fetal head, the patient was treated

with the toxines for three months, and the tumor had then shrunk to two thirds of its original size. The patient, out of patience with the long duration of the treatment, decided to call in a surgeon, who operated with a fatal result. In a case of recurrent sarcoma of the arm the injections checked the growth of the tumor only temporarily. In one of sarcoma of the pharynx no result was noted other than a brief restraint of the growth.

The sixth case was one of deeply ulcerated sarcoma of the neck in a very debilitated man, sixty-four years old, who died during the reaction following an injection of ten cubic centimetres of the toxines after the treatment had been carried on for five weeks. The tumor had diminished in volume a little. The seven other cases were all examples of epithelioma or carcinoma, and, save in two of these, the results were but very slight. In one of these two, a recurrent carcinoma of the breast, the injections seemed to check the growth of the tumor, for it remained stationary for several months; in the other, a uterine carcinoma, there was alleviation of the pain together with reduction of the size of the tumor, and the improvement lasted for four months.

Such results as Dr. Matagne has reported certainly ought to encourage Dr. Coley to persevere in his labors. It is evident, we think, that the toxine treatment is of some value, more particularly in cases of sarcoma; the problem is to ascertain the class of cases in which it holds out a distinct promise of proving decidedly palliative if not curative.

### MINOR PARAGRAPHS.

#### THE FIFTIETH ANNIVERSARY OF THE INTRODUCTION OF ANESTHESIA.

INTERESTING ceremonies may be expected to take place in the Massachusetts General Hospital, in Boston, on the 16th of October, in commemoration of the fiftieth anniversary of Morton's first public demonstration of surgical anesthesia, which was made in the operating theatre of that hospital on October 16, 1846.

#### HEMORRHAGIC CONTRACTURAL MYXODERMIA.

This seems to be the equivalent of a French name given by M. Brun (*Bulletin de l'Académie de Médecine*, 1893, No. 19) (*Procès-verbal pour l'année Médicale*, September 5, 1893) to a disease which sets in suddenly with high fever, malaise, vomiting, and headache, followed by delirium and restlessness. The fever continues for about eight days with the temperature ranging from 102° to 104° F., and then, with remissions, a second and a third febrile period occur. There are contractures of the most varied groups of muscles; there is a peculiar doughy condition of the skin, and there are subcutaneous hemorrhages. There is no meteorism or roseola. The disease lasts

from three to four weeks. The nature of this manifestly infectious disease is not yet understood.

#### THE CHARLOTTE MEDICAL JOURNAL.

The editors of this North Carolina monthly journal, Dr. Register and Dr. Montgomery, are much to be commended for having brought it to a high station among the medical journals of the country. Each number contains a great amount of matter of good quality. We are glad to learn that it is meeting with the appreciation it merits.

#### ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 15, 1896:

DISEASES.	Week ending Sept. 8.		Week ending Sept. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	35	6	44	14
Scarlet fever.....	22	3	27	2
Cerebro spinal meningitis....	0	0	3	4
Measles.....	24	3	42	5
Diphtheria.....	132	27	121	33
Tuberculosis.....	151	83	185	111

**The Castration of Criminals.**—We emphatically indorse the following, which appeared in the *Medical Record* for September 12th:

"In a paper entitled *The Crimes of Medical Men*, in the *Medical Herald* for June, 1896, Dr. W. O. Henry mentions as one of the crimes of which some, no doubt many, of us are guilty is a failure to urge legislation to prevent the marriage of criminals, or to have them castrated. Whether we are to regard such a failure as wrong or not must depend entirely upon whether or not we think the 'proposed remedy is one that will the most surely prevent crime.'

"As to forbidding marriage, most persons of the class referred to are married before they become confirmed drunkards or are known as habitual criminals; moreover, it is by no means certain that they would procreate less if they were not married and had their liberty.

"Castration of the 'rapist' might fit in with the sense of justice as well as with that of retaliation of most people, but if the community should reach the conclusion that drunkards and criminals should not leave descendants, it would seem that an effectual means to that end could be found aside from depriving them of organs which are so important as to be characteristic of sex, and which, it is more than likely, are essential in some respects to normal mind and physical health. And then, who shall say that the drunkard and the criminal have fallen so low that they ought, as a result of mutilation, to be deprived forever of the possibility of redemption through woman's purifying influence? The reason for making a general law condemning these unfortunate to castration is suggested solely by judgment based presumably upon facts, but the facts are not all in, or are too uncertain in their application to assure a whole profession that the judgment is final. But if it were proved that procreation by these persons is so baneful to society as to justify steps effectually to stop it, the end could be reached simply by such restraints as would prevent the sexual relation, while incidentally the criminal would be made to forego his crimes and the drunk and his debaucheries. Then, in the event of a mistake having been made by the community, it would not be impossible to undo the injury."

**An Illustrated Lecture on Roentgen Rays.**—On Friday evening, September 25th, a lecture will be given, in Association Hall, Fourth Avenue and Twenty-third Street, by Mr. Max Osterberg, E. E., A. M., on *The Possibilities and Limitations of the Röntgen Rays*. Mr. Osterberg, who is

well known as an electrical expert, is the instructor in the evening class in electrical engineering at the Twenty-third Street Branch of the Young Men's Christian Association, and has kindly volunteered his services for this lecture. The proceeds will be devoted to securing apparatus with which to illustrate the instruction in the class-room. Besides exhibiting and explaining the Röntgen-ray apparatus, Mr. Osterberg will illustrate his lecture throughout with a stereopticon lantern. The price of admission will be fifty cents. Tickets may now be secured at the office of the Young Men's Christian Association, No. 52 East Twenty-third Street.

**The Buffalo Academy of Medicine.**—At the last regular meeting of the Section in Pathology, on Tuesday evening, the 15th inst., the following papers were read: *Acute Aortitis*, by Dr. De Lancey Rochester, and *Interstitial Pancreatitis*, by Dr. H. G. Metzinger. Specimens were exhibited by Dr. Eugene A. Smith and Dr. Chauncey P. Smith.

**Erratum.**—An esteemed correspondent calls our attention to a manifest error in a therapeutical note on *duboisine* published in our last issue, on page 363. From a quarter to a third of Pravaz syringeful of a forty-per-cent. solution is given as the dose. As our correspondent suggests, the mistake is so palpable as to deprive it of danger.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 6 to September 12, 1896:*

The following named officers will report in person on Tuesday, September 22d, at 10 o'clock A. M., to ALDEN, CHARLES H., Colonel and Assistant Surgeon General, president of the examining board appointed to meet at the office of the Surgeon General, United States Army, for examination as to their fitness for promotion: APPEL, AARON H., Captain and Assistant Surgeon; BANISTER, JOHN M., Captain and Assistant Surgeon; BRECHEMIN, LOUIS, Captain and Assistant Surgeon; DAVIS, WILLIAM B., Captain and Assistant Surgeon; GRAY, WILLIAM W., Captain and Assistant Surgeon; LA GARDE, LOUIS A., Captain and Assistant Surgeon. LA GARDE, LOUIS A., Captain and Assistant Surgeon, is relieved from duty as attending surgeon and examiner of recruits at Boston, to take effect upon the completion of his examination, and ordered to Fort Robinson, Nebraska, for duty.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending September 12, 1896:*

STOKES, C. F., Passed Assistant Surgeon. Orders of July 21st modified: detached from duty as member of the naval and medical examining boards, New York, and ordered to continue as recorder.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Sixteen Days ending August 31, 1896:*

BAILHACHE, P. H., Surgeon. Detailed to represent the service at the meeting of the American Public Health Association, August 24, 1896.

PURVANCE, GEORGE, Surgeon. Relieved from duty at Philadelphia, Pa., and directed to proceed to St. Louis, Mo., and assume command of service. August 25, 1896.

HAMILTON, J. B., Surgeon. When relieved from duty at Chicago, Ill., to proceed to San Francisco, Cal., and assume command of service. August 25, 1896.

GASSAWAY, J. M., Surgeon. Granted leave of absence for thirty days from October 1, 1896. August 24, 1896.

GODFREY, JOHN, Surgeon. When relieved from duty at San Francisco, Cal., to proceed to Chicago, Ill., and assume command of service. August 25, 1896.

WHEELER, W. A., Surgeon. When relieved from duty at Ellis Island, New York, to proceed to Cincinnati, Ohio, and assume command of service. August 25, 1896.

BANKS, C. E., Surgeon. To proceed from Washington, D. C., to Boston, Mass., for temporary duty. August 21, 1896.

CARMICHAEL, D. A., Passed Assistant Surgeon. Granted leave of absence for thirty days from September 5, 1896. August 17, 1896.

WASDIN, EUGENE, Passed Assistant Surgeon. Granted leave of absence for five days. August 25, 1896.

BROOKS, S. D., Passed Assistant Surgeon. Directed to rejoin station at St. Louis, Mo., and when relieved from duty at that place to proceed to Port Townsend, Washington, and assume command of service. August 25, 1896.

WHITE, J. H., Passed Assistant Surgeon. Relieved from special duty at Key West, Fla., and directed to rejoin station at New York, N. Y. August 24, 1896. Detailed for duty in connection with immigration service at Ellis Island, N. Y. August 25, 1896.

CARRINGTON, P. M., Passed Assistant Surgeon. To proceed to Chicago, Ill., and assume temporary command of service. August 25, 1896.

KINYOUN, J. J., Passed Assistant Surgeon. Detailed to represent the service at the meeting of the American Public Health Association. August 24, 1896.

PERRY, T. B., Passed Assistant Surgeon. Detailed to represent the service at the meeting of the American Public Health Association. August 24, 1896.

VAUGHAN, G. T., Passed Assistant Surgeon. Detailed for duty in connection with immigration service at Philadelphia, Pa. August 25, 1896.

COBB, J. O., Passed Assistant Surgeon. When relieved from duty at Cincinnati, Ohio, to proceed to New York, N. Y., for duty. August 25, 1896.

STIMPSON, W. G., Passed Assistant Surgeon. Relieved from command of service at Port Townsend, Washington, on arrival of Passed Assistant Surgeon S. D. Brooks. August 25, 1896.

SPRAGUE, E. K., Assistant Surgeon. When relieved from duty at New York, N. Y., to rejoin his station at Boston, Mass. August 27, 1896.

CUMMING, H. S., Assistant Surgeon. When relieved from duty at Norfolk, Va., to proceed to Evansville, Ind., for temporary duty. August 25, 1896.

GREENE, J. B., Assistant Surgeon. To proceed from Baltimore, Md., to Cleveland, Ohio, for temporary duty; upon completion of which to rejoin station. August 25, 1896.

#### Society Meetings for the Coming Week:

MONDAY, *September 21st*: New York Academy of Medicine (Section in Ophthalmology and Otology); Hartford, Connecticut, Medical Society; Chicago Medical Society; Cleveland Society of the Medical Sciences.

TUESDAY, *September 22d*: American Association of Obstetricians and Gynecologists (first day)—Richmond, Virginia); New York Dermatological Society; Metropolitan Medical Society, New York (private); Buffalo Academy of Medicine (Section in Obstetrics and Gynecology); Medical Society of the County of Lewis (quarterly), N. Y.; Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, *September 23d*: American Association of Obstetricians and Gynecologists (second day); New York Academy of Medicine (Section in Laryngology and Rhinology); New York Pathological Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany, N. Y.; Philadelphia County Medical Society.

THURSDAY, *September 24th*: American Association of Obstetricians and Gynecologists (third day); New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Massachusetts, Society for Medical Improvement (private); Pathological Society of Philadelphia (conversational).

FRIDAY, *September 25th*: American Academy of Railway Surgeons (first day—Chicago); New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association, New York (private); Philadelphia Clinical Society; Philadelphia

Laryngological Society; St. Louis Academy of Medical and Surgical Sciences; Cleveland Medical Society. SATURDAY, *September 26th*: American Academy of Railway Surgeons (second day); St. Louis Medical Society.

#### Answers to Correspondents:

No. 471.—It is proper to write either *Röntgen* or *Roentgen*. The word is accented on the first syllable; the *o* in *oer* has the sound of the *o* in *her*, and the second syllable is pronounced *gen*.

### Births, Marriages, and Deaths.

#### Married.

BISCHOF—BALTZ.—In Buffalo, on Wednesday, September 9th, Dr. Henry Bischof and Miss Hattie Baltz.

BOUYER—RICHARDSON.—In Pensacola, Florida, on Wednesday, September 9th, Mr. André Bouvier and Miss Ella Richardson, daughter of Dr. W. Richardson, of Jeanerette, Louisiana.

LOMAX—SWEET.—In New Baltimore, N. Y., on Thursday, September 17th, Dr. Howard E. Lomax and Miss Jennie A. Sweet, daughter of the Hon. Newton Sweet.

PIERCE—MILLER.—In Chester, N. Y., on Wednesday, September 9th, Dr. Louis R. Pierce, of Newburgh, N. Y., and Miss Mary S. Miller.

RITTER—HOLLAND.—In Kansas City, Missouri, on Tuesday, September 15th, Dr. Caleb Anderson Ritter and Miss Mary Helen Holland.

#### Died.

ALDRICH.—In Fall River, Massachusetts, on Tuesday, September 8th, Dr. James M. Aldrich, aged seventy-nine years.

FIFIELD.—In Dorchester, Massachusetts, on Wednesday, September 9th, Dr. W. C. B. Fifield, aged sixty-eight years.

LEE.—In Summerville, South Carolina, on Wednesday, September 9th, Dr. H. B. Lee.

MULFORD.—In New York, on Wednesday, September 9th, Dr. Sylvanus S. Mulford, aged sixty-six years.

### Obituaries.

#### WILLIAM M. McLAURY, M. D.

DR. McLAURY was born in North Kortright, Delaware County, New York, on August 22, 1830. His ancestors, Scotch-Irish, settled in New York State in 1765. He received an academic education and came to New York in 1853, taught school and studied medicine, graduating from the University of the City of New York in March, 1860. His skill and devotion to his profession soon acquired for him a large and lucrative practice. In his success he never forgot the poor. His kindly disposition, his warm heart, and the interest he took in all who were suffering endeared him to those who came in contact with him, whether as friends, acquaintances, or patients. His writings on medical and ethical subjects have attracted wide and favorable mention. He was a member of the New York County Medical Society, the Academy of Medicine, the Northwestern Medical and Surgical Society, and the New York Physicians' Mutual Aid Association. He leaves a widow, one son, Dr. Frank H. McLaury, and a daughter.

## Proceedings of Societies.

### AMERICAN GYNÆCOLOGICAL SOCIETY.

*Twenty-first Annual Meeting, held in New York, on Tuesday, Wednesday, and Thursday, May 26, 27, and 28, 1896.*

The President, Dr. WILLIAM M. POLK, of New York, in the Chair.

*(Continued from page 169.)*

**Suspensio Uteri with Reference to its Influence upon Pregnancy and Labor.**—In the discussion of Dr. Noble's paper on this subject, Dr. T. A. EMMET, of New York, said that, as he had recognized at the outset that Alexander's operation prolapsed the uterus at the same time that it anteverted it, he had never done the operation, and, as he had been able to relieve all his patients by plastic surgery, he had seen no occasion for either Alexander's operation or *suspensio uteri*.

Dr. G. M. EDEBOHLS, of New York, said that experience had shown that the only effect of Alexander's operation on subsequent pregnancies was to cause a slight dragging pain near the termination of pregnancy. Although vaginal fixation was a young operation, it had already caused an appalling list of complications of subsequent labors. Ventral fixation occupied a position between the two, although a number of disasters in connection with parturition had been reported after it. In his own experience there had been eight pregnancies after ventral fixation, and two deaths, but one of these deaths had occurred just before the onset of labor, and the second was in no way due to the ventral fixation. The lower the attachment and the more secure it was, the better the gynæcological result, but the worse the results in case of the occurrence of pregnancy. Probably the best method of attachment was to secure it squarely by the fundus in a position in which the uterus would naturally rest without dragging on the lower attachment.

Dr. H. A. KELLY, of Baltimore, said that he had been able to secure reports from forty-six married women upon whom he had performed this operation. Among them there had been thirteen pregnancies, and in only one had the labor been at all difficult. This was one of his early cases, and as a result of sloughing very extensive and firm adhesions had formed between the uterus and the abdominal wall. The method which he had originally described, and which he had successfully followed in about two hundred and fifty operations, seemed to him the best. His method was to pass two silk sutures through the peritoneum and through the uterus just posterior to the ridge on the top of the fundus. He had fixed the uterus in his cases both low and posteriorly, and yet, contrary to what Dr. Edebohls had stated, the fixation had been firm and the results satisfactory.

Dr. A. LAPHORN SMITH, of Montreal, said that out of fifty cases in which he had performed the operation according to Kelly's method, the only difficulty in subsequent pregnancy had been one abortion at the fifth month. He thought it was well not to use too coarse a suture, and to follow Kelly's suggestion of not taking in too much of the abdominal wall. In some cases he had done ventral fixation where there were firm adhesions and extensive disease of the appendages, and had relieved these women of the pain from which they had long suffered, simply by elevating the ovaries and tubes to their proper level.

Dr. ASHURON thought that the statistics collected regarding the obstetrical relations of the operation of *suspensio uteri* were of but little value, owing to the fact that they took no cognizance of the different modifications of procedure, and hence ignored the very important factor of the degree of fixation of the uterus. Our aim should be not only to suspend the uterus, but to tilt it a little forward, and this could only be done by taking advantage of the peritoneal attachment of the new adhesions. In two cases in which he had had occasion to perform abdominal section subsequent to the operation of *suspensio uteri*, he had found the uterus united to the abdominal wall only by a slender band of adhesion about two inches in length. Such a long adhesion would be formed where the suture was passed through the peritoneum. He had not seen these cases of retrodisplacement cured, as Dr. Emmet had, by plastic surgery and the use of pessaries.

Dr. HENRY D. FRY, of Washington, said that not long ago he had seen a woman, about five months pregnant, upon whom ventral fixation had been performed nearly four months previously. He had ascertained that she had gone through the rest of her pregnancy and her labor without trouble, and had been delivered of a child weighing six pounds and a half. He had himself recently performed ventral fixation on a woman, ten weeks pregnant, to liberate an incarcerated uterus. It seemed to him that in estimating the influence of this operation on subsequent labors we should take into consideration the interval between the ventral fixation and the occurrence of conception. Obviously, there would be less chance of interference with parturition if sufficient time had elapsed to allow of the formation of a long and slender adhesion between the uterus and the abdominal wall.

**The Diagnosis and Treatment of Ureteritis in Women.**—Dr. EDWARD P. REYNOLDS, of Boston, read a paper on this subject. He said that the physical signs of ureteritis were very poorly defined and were consequently often overlooked. The two most characteristic symptoms of ureteritis were: 1. Frequency of micturition, increased by the erect posture; 2. a bearing-down pain, increased by standing, but usually completely relieved by a few hours of rest in bed. These symptoms, of course, might result from other causes, but the combination of them pointed very strongly to this affection. The physical signs elicited by vaginal examination were tenderness and a desire to urinate when pressure was made over the vaginal portion of the ureter. Cystoscopic examination would show alteration of the vesical orifice of the ureters. The appearance of the vesical orifice of the inflamed ureter varied from a slight redness and gaping to a decided eversion of the mucous membrane. The adjacent vesical mucous membrane was often reddened and eroded. In eight cases of ureteritis in which he had catheterized both ureters the percentage of urea had in every case been decreased in the urine obtained from the affected side. Of course, these observations were yet too few to admit of any definite conclusions, but the point seemed to him worthy of note. The treatment was palliative and curative. In cases in which the vesical mucous membrane and the ureteral orifice were inflamed, he had always given relief by strictly localized applications of the solid nitrate of silver to the inflamed areas. The relief so obtained was, of course, only symptomatic and temporary. In the curative treatment of ureteritis, we were forced to rely upon regulation of the diet. The patient should

be made to take three or four pints of bland water, and this might be supplemented by an alkaline diuretic. Asparagus and strawberries should be absolutely interdicted. Other fruits should be used sparingly, and the highly flavored vegetables, such as onions, should be tried cautiously. He said that he had seen but little benefit from the use of other drugs than alkalies until he had discovered that the urine from the affected ureter was deficient in urea. This fact had led him to think that probably the renal insufficiency was due rather to a deficiency in the metabolism of the body as a whole than to a defect in the kidneys themselves. Under such circumstances, it was probable that the urine contained some irritant. Small doses of iodide of potassium and mercury having been recommended last year by Dr. Etheridge in renal insufficiency, he had tried this treatment in ureteritis, and had so far been greatly pleased with the results. He believed that ureteritis was often mistaken for intestinal colic, the pain due to renal stone, or acute catarrhal salpingitis. The abdominal pain was often quite severe and was usually intermittent. At the beginning of the attack there would be renal tenderness on deep pressure, and later on it would be very distinctly located at McBurney's point. Still later a new spot of tenderness would be found at a point about an inch above Poupart's ligament. From this time on, vaginal examination would reveal the characteristic tenderness and usually a distinct swelling of the vesical end of the ureter. The affection tended toward recovery.

**Implantation of the Ureter in the Bladder.**—Dr. H. J. BOLDT, of New York, read a paper on this subject. He said that if, after a pelvic operation, ischuria, colicky pain, and tenderness over one kidney were present, a cystoscopic examination should be made. On the insertion of the ureteral catheters, no urine will flow from that ureter that had been wounded or occluded by a ligature or clamp. If during an operation it was discovered that the ureter had been injured, a ligature should be immediately applied to the distal end and the proximal end implanted in the bladder. The method of implantation which he recommended was to be performed as follows: A ureteral catheter having been inserted into the injured ureter, the bladder was temporarily distended with sterile water to facilitate the selection of the spot for the implantation, and an incision about an inch long was made into the bladder. As the knife touched the mucosa, the water in the bladder was allowed to escape by means of a catheter. A long dressing forceps was then introduced through the urethra and out through the artificial opening in the bladder, where it seized the ureteral catheter and drew it back into the bladder and out of the urethra. The ureter was next invaginated through the bladder wound, and several very fine silk sutures were passed quite superficially through the ureter, but through the bladder wall with the exception of the mucosa. After the abdomen had been closed, a permanent catheter was allowed to remain in the urethra alongside of the ureteral catheter, so as to keep the bladder empty. After forty-eight hours the ureteral catheter should be removed. Where it was impossible to do an implantation, nephrectomy might be done as a last resort.

Dr. M. D. MANN, of Buffalo, said that the difference in the urea excreted in the two ureters in cases of ureteritis might perhaps be explained by reflex action. That the irritation of the bladder around the mouths of the ureters was the cause of the symptoms had been exam-

plified in one of his cases, in which there had been an extensive ureteritis with absolutely no symptoms of vesical irritation. He had found that the treatment of the inflammation of the trigone and of the region around the ureteral orifices by applications of nitrate of silver gave more relief than anything else. He was afraid to irrigate the ureter, for there was great danger of causing infection or traumatism. While chronic ureteritis was much more commonly met with than the acute form, the latter was sometimes observed, more especially after labor. The acute cases coming on as a result of lithemia were often overlooked. He had become convinced that much of the pelvic pain experienced by women was due to irritation set up by the passage of abnormal and irritating urine through the ureters. Some of the most obstinate cases could be cured by plenty of exercise, proper habits of life, and the ingestion of large quantities of water.

Dr. E. P. DAVIS, of Philadelphia, remarked that he had found certain abnormal conditions of urine in women prove very obstinate under treatment until he had discovered that they had been kept up by the habit of chewing tea leaves.

Dr. A. LAPHORN SMITH said that he looked upon ureteritis as a local disease dependent upon an abnormal condition of the urine. Our treatment should be directed to the prevention of the formation of such irritating products of deficient oxygenation as uric acid and oxalic acid. The urine should be made alkaline and bland by the free use of water and alkalies, the diet should be properly restricted, and plenty of exercise enjoined.

Dr. REYNOLDS said that there was great danger of making false passages by attempts at exploring the ureters with rigid instruments. The administration of small doses of mercury he had found of the greatest benefit in those rare cases of uræmia in pregnancy in which the urine was abundant and of low specific gravity. He believed that we should eventually learn that ureteritis was secondary, usually to some disturbance of the kidney.

**Intestinal Bacteria as a Source of Infection Complicating Obstetric Operations.**—Dr. EDWARD P. DAVIS, of Philadelphia, reported two cases of fatal ptomaine poisoning due to intestinal bacteria. The first was that of a girl of twenty-one years who, after labor, had typhinites, vomiting, and high temperature, and died after five or six days. The autopsy showed numerous intestinal ulcers swarming with the colon bacillus and the *Micrococcus pyogenes albus*. There was no evidence of sepsis. The second case also occurred in a young girl who, immediately after labor, had a high temperature and a rapid pulse, without chill, and who afterward became maniacal. The use of the curette and of antiseptic douches did not affect the symptoms. The autopsy showed an abnormal loop of the large intestine full of inspissated feces, and evidently the source of the infection. He said that Dr. Bevan had found, on searching the records of three hundred autopsies, that such a loop of bowel had been noted in eighteen cases. In fourteen of these there had been a history of insanity; two of the patients committed suicide and two were unconscious at the time of their death.

Dr. ROBERT A. MURRAY, of New York, reported several cases apparently bearing out the view that occasionally fatal infection might result from absorption of the products of intestinal bacteria. He thought the best antiseptic cathartic was calomel.

Dr. GRANDIN, of New York, was afraid that this paper might lead some to rest satisfied with the diagnosis of intestinal infection and toxæmia when in reality the condition was one of puerperal sepsis. These cases certainly emphasized the importance of keeping the gravid woman under medical supervision from the very beginning of pregnancy up to the time of labor.

Dr. CUSHING, of Boston, said that the symptoms presented in the cases reported in the paper were those which had long been recognized by abdominal surgeons as indicative of intestinal toxæmia—indeed, this had led to the treatment of supposed septic peritonitis by saline purgatives.

Dr. DAVIS said that he had based the diagnosis on the comparatively low temperature, the very high pulse, the absence of chill, and the fact that the milk came in properly and the patient retained her appetite. For quickly rendering the intestine aseptic, perhaps the best treatment was the administration of one two-hundredth of a grain of bichloride of mercury several times a day for a number of days, and following this by saline purgatives.

**The Treatment of Intraligamentous and Retroperitoneal Uterine Fibromyomata.**—Dr. WILLIAM H. WATHEN, of Louisville, said that whenever it was possible he removed small tumors through the vagina, enucleating them from the broad ligament or the uterine wall, without removing the appendages. In the special class of tumors forming the subject of his paper he advised separating the vagina from the cervix, ligating or clamping the uterine arteries, if possible in continuity near the pelvic wall. The lower part of the uterus might then be separated from its attachments, after which the operation could be completed through the abdomen. The adhesions having been separated, the ovarian arteries should be ligated close to the pelvic wall, thereby practically cutting off all the blood supply to the uterus or tumors. The capsule should be sutured in the lower part of the abdominal wound and the incision closed above. Ordinarily there would be no sutures or ligatures left in the peritoneal cavity, except the two on the ovarian arteries. The same method might be followed in the removal of other forms of uterine myomata.

Dr. CUSHING said that when the tumors developed behind the peritonæum and under the broad ligament it was usually because they had their origin in the cervix, and hence they might be below the uterine arteries. He thought that by simply splitting the capsule of such tumors, they could usually be enucleated readily.

Dr. P. A. HARRIS, of Philadelphia, regretted that he had not known of this valuable method some time ago while engaged in operating on a difficult case of this kind.

Dr. GORDON, of Portland, Maine, said that he was in the habit of doing the vaginal operation first and ligating the uterine arteries, and then completing the operation through the abdomen.

Dr. J. T. JOHNSON, of Washington, suggested that a lateral flap could be made, and so allow the dangerous adhesions to slip away. We could then close the wound by a continuous suture.

The PRESIDENT said that these intraligamentous growths laid bare the origin of the uterine, vesical, and vaginal arteries. By securing the anterior trunk of the internal iliac, by the method employed in the old operation for aneurysm of the internal iliac artery, it was easy to control the blood supply to the field of operation. Experience after ligation of this artery for aneurysm, and

the knowledge of the free collateral circulation established through the middle hæmorrhoidal artery were a sufficient guarantee of the safety of thus cutting off such a large supply of blood at one time.

Dr. WATHEN said that he had referred to the ligation of the uterine arteries *per vaginam*, and had suggested that the ligation should be near the origin of the arteries.

**Cæsarean Section; Suture of the Uterus versus Total Extirpation.**—Dr. HENRY C. COE, of New York, in a paper with this title, said that it was his purpose to extend the indications originally laid down for the Porro operation, in strict accordance with the teachings of modern surgery. He had felt that the three cases of Cæsarean section already reported by him, although surgically successful, had been of doubtful benefit to the patients, because of the preservation of the uterus. He then reported an additional case in which, owing to the condition of the mother, he had believed it to be imperative to complete the operation as rapidly as possible and had, therefore, chosen total extirpation of the uterus. In connection with this case, it seemed to him that while it was most desirable to preserve the functions of menstruation and ovulation whenever possible, it should be remembered that the uterus and annexa were often sacrificed in cases of fibroids, where there was a far less menace to life than a second pregnancy was in a woman in whom there was an absolute impediment to natural delivery. To avoid another pregnancy, one could ligate the tubes or remove the annexa, but experience had demonstrated that nothing short of extirpation of the uterus afforded positive immunity from future impregnation.

Dr. GRANDIN said that where the uterus was infected or contained fibroids we were justified in performing hysterectomy, but beyond this he could not go. In his opinion, it was not the business of the medical man to look into the future and ligate the tubes or extirpate the uterus because at some future time the woman might become pregnant.

Dr. GEORGE T. HARRISON, of New York, said it did not seem to him right to remove healthy tubes and ovaries because of possible future complications, but where there was a probability that the uterus had been infected hysterectomy was proper.

Dr. NOBLE thought most of those present would agree that hysterectomy was proper where the uterus was infected or where there were so many fibroids that it did not seem probable that myomectomy could be done at another time. He could not agree with the reader of the paper that it was our business to remove the appendages simply because the patient could not have a baby in the natural way.

Dr. R. A. MURRAY was of the opinion that this ethical question did not concern the physician, and that therefore he should not attempt to decide it. He would favor doing a Cæsarean section and a subsequent operation for fibroids or other disease, if such should be required. If it could be demonstrated that infection had already occurred at the time of the Cæsarean section, then the uterus should be removed by all means.

Dr. HARRIS thought it was too radical to assume that because the woman had not had the best of care at first one must remove the uterus to anticipate sepsis.

Dr. DAVIS held it to be the right of a woman who was in a condition rendering natural delivery impossible to say to the obstetrician that, if the risk was no greater from stopping procreation than from refraining from

doing so, procreation should be stopped. He believed that under such circumstances it was the duty of the obstetrician to give the patient the power of volition.

Dr. H. J. BOLDR said that if the patient had not stated her desire in the matter, he would remove the uterus entirely, particularly if fibroids were also present.

Dr. H. J. GARRIGUES, of New York, protested that women had not the right to ask to be made sterile. This must be left to Nature or to God, but certainly not to the physician. Where the mother was in an advanced stage of tuberculosis, it seemed to him that the child's right should be considered, and that we should save children as far as possible from such a maternity.

Dr. COE said that he had not intended to convey the impression that he would remove the uterus recklessly and without the patient's consent, just as many some years ago had removed the ovaries; but he did think that in these operations we must look into the future, particularly in cases of illegitimate pregnancy occurring in miserable, ignorant, and sickly mothers.

#### **Drainage of the Stump in Abdominal Hysterectomy.**

—Dr. HENRY T. BYFORD, of Chicago, reported sixty-eight cases in which he had provided drainage through the vagina in various ways. Three of these patients only had died, and he was of the opinion that had he not established this drainage there would have been in this series at least twice as many deaths.

Dr. NOBLE said that his experience, both with and without drainage, would lead him to believe that the drainage so carefully provided by Dr. Byford was unnecessary.

**Myomectomy; Fatal Secondary Hæmorrhage with Rising Temperature.**—Dr. HENRY D. FRY, of Washington, reported a case of myomectomy in which he had been led away from the correct diagnosis of internal hæmorrhage by the elevation of temperature. The hæmorrhage had lasted for twenty hours before it had proved fatal, but following the teachings of the text-books he had looked for a subnormal temperature under such circumstances. At the autopsy the peritoneal cavity was found filled with blood and without evidence of sepsis or other complication.

Dr. GRANDIN took the ground that the pulse was a much better guide than the temperature to the occurrence of hæmorrhage, as it was also to that of sepsis. A very rapid fall of temperature, associated with increasing rapidity of the pulse, should be taken as an indication of intra-abdominal hæmorrhage.

Dr. J. M. BALDY, of Philadelphia, expressed the same opinion, and added that when the temperature was subnormal in a case of severe hæmorrhage death was imminent.

Dr. A. LAPHORN SMITH thought that the best sign we had of internal hæmorrhage was a *sudden* increase in the pulse rate.

Dr. DR. BOISE, of Grand Rapids, said that when there was a gradual hæmorrhage into the peritoneal cavity the effort of the peritonæum to dispose of the effused blood was usually indicated by an elevation of the temperature.

Dr. DAVIS said that the temperature elevation might be explained in this way or by the existence of a slight adhesive peritonitis. In abdominal sepsis the pulse was apt to fall and the temperature to rise, whereas in gradual internal hæmorrhage there was a gradual rise of both temperature and pulse.

**An Electrode for burning off Ligatures.**—Dr. CLEMENT CLEVELAND, of New York, exhibited a small platinum-loop electrode which he had found useful in liberat-

ing the ligatures after vaginal hysterectomy. One such electrode was tied in with the ligature, and when it was desired to remove the latter it was only necessary to pass an electric current through the electrode.

**Surgical Injuries of the Ureter.**—Dr. J. MONTGOMERY BALDY, of Philadelphia, in a paper on this subject, said that uretero-ureteral anastomosis was only suitable in a small proportion of cases, and the danger of immediate obstruction seemed very great. Should stenosis occur subsequently it would be more easily detected and treated after uretero-cystostomy—indeed, all the evidence seemed to be rather in favor of uretero-cystostomy in preference to uretero-ureteral anastomosis.

Dr. BACHE McE. EMMET, of New York, thought there would be in all cases great risk of infection of the kidneys, and that this danger would be greatly enhanced where there was cystitis. Whether the anastomosis was made at the bladder or along the line of the ureter, he could not but feel that there would be a backward pressure, and consequently a danger of establishing nephritis.

Dr. BYFORD was of the opinion that the attachment of the ureter to the bladder would be apt to interfere with the contraction of this viscus. If the method of lateral anastomosis described by Kelly proved to be as successful as the other operations mentioned, he thought it should be given the preference.

### COLLEGE OF PHYSICIANS OF PHILADELPHIA.

#### SECTION IN OPHTHALMOLOGY.

*Meeting of March 17, 1896.*

The Chairman, Dr. WILLIAM F. NORRIS, presiding.

**Traumatic Enophthalmia.**—Dr. GEORGE C. HARLAN exhibited a five-year-old boy who five months previously had been wounded by the horn of a bull. The right cheek and temple and the lower eyelid were lacerated, and the inferior margin of the orbit was chipped. There was also complete ptosis. At the time of examination, the tendo oculi was found to have been torn away and the lower lid was dragged downward and outward by the action of the orbicularis and the contraction of the cicatrix.

The surgeon who attended the patient at the time of the accident reported that there was considerable orbital cellulitis with abundant discharge of pus from between the lids, but there never was any exophthalmia. He thought that the cellulitis was confined to the lower part of the orbit. At present the eyeball was retracted and had the appearance of being very much smaller than its fellow. The cornea was situated five millimetres behind the plane of that of the other eye. There was scarcely more ptosis than would result from the depression and loss of support of the lid. When the patient looked directly forward, the palpebral fissure was five or six millimetres wide. He insisted that he saw well with the eye. Though the movements of the eyeball were much restricted, no diplopia could be detected. There was complete inability to look upward beyond the horizontal line either directly or to the right or left. Horizontal movements were normal and the downward excursion was much exaggerated.

Dr. GEORGE FRIBUS spoke of his case of traumatic enophthalmia seen nine years ago, in which there had been sufficient recovery to manifest but little difference between the two eyes; there was nothing left except a

slight doubling of objects when looked at below the horizontal line. In his case there was no incarceration of the extra-ocular muscles.

**Unicocular Retinal Detachment with High Myopia.**—Dr. FRANCIS M. PERKINS presented a case.

**Ciliary Staphyloma and Excavation of the Optic Disc following Traumatic Cataract.**—Dr. CHARLES A. OLIVER gave the clinical history of a case in a four-year-old boy. The clinical picture of this case of complicated secondary glaucoma was so complete, having been studied from what might almost be termed its very incipency to the final result, and the varying symptoms evolved from time to time were so at variance with what one would expect in such cases, that it offered itself as a most interesting and a most instructive study of this type of disease.

Unlike similar cases of sudden obstruction to proper lymph-stream circulation, there remained from the very first, as shown by the fields of vision, and as afterward proved ophthalmoscopically, an element that might possibly complicate many more cases of the traumatic type of this disease than was at present imagined, namely, retinal detachment. Again, the condition of the vitreous and the peculiarity of its opacities, taken in connection with the history of the case, would go far to show that there had been a hæmorrhage into that humor which most probably might have been recognized ophthalmoscopically had the patient been seen a week earlier. These, with a few though certain evidences of a low grade of iridocyclitis, made the case still more atypical.

On the other hand, the progressive diminution of the field of vision, the gradual distention of the globe, the localized tissue-bulgings in the upper ciliary regions, the deep and characteristic cupping of the nerve-head, the reapproximation of the remaining areas of retinal detachment, and the late fixedly increased intraocular tension, all showed the certainty of degeneration even in a young and yielding eyeball, when such tissues were subjected to a persisting increased intraocular pressure.

As to an answer to the vexed question of treatment in such cases, the author would leave this for another and more extended communication, reserving the present brief though detailed account of the clinical history as an interesting and useful exposition of a grouping of symptoms which had been carefully studied and could be thus employed to illustrate the results of two conflicting contemporaneous conditions produced by traumatism—localized inflammatory reaction and obstruction of lymph-stream circulation.

**A Further Note on an Unusual Form of Macular Lesion following Iritis** was presented by Dr. GEORGE E. DE SCHWEINITZ. The patient, a fifty-year old woman, had recovered with a nearly normal sharpness of vision, but with some vitreous opacities, from a violent attack of serous iritis. The eye had remained comfortable for eight months, when she appeared with a positive scotoma and the ability to see to count fingers only when situated in the periphery of the visual field. In addition to the positive scotoma, which the patient described as appearing "like a dinner plate with a green edge," there was a small absolute scotoma at about the horizontal level. Ophthalmoscopic examination revealed an oval reddish area, giving the impression of a disintegrating hæmorrhage and containing in the centre several white dots situated exactly in the centre of the macular region. Dr. de Schweinitz referred to the unusually distinct macular ring, which seemed to indicate that there must be some thickening in the periphery of the hæmorrhagic area.

**An Unusual Submacular Hæmorrhage.**—Dr. OLIVER exhibited a water-color sketch of a case of unusual submacular hæmorrhage forming a part of some very curious lymph extravasations in the retina without any vitreous disturbances, found in the left eye of a healthy sixty-five-year-old woman upon whom he had successfully operated for black cataract by simple extraction some two months previously, the operation being perfectly smooth and the appearance of the interior portion of the eye normal in every respect. The sketch had been made for him by Miss Margaretta Washington.

**Convergent Strabismus and Very High Myopia.**—Dr. DE SCHWEINITZ gave the clinical history of a patient suffering from convergent strabismus of the left eye and a very high myopia, 16 D. Ophthalmoscopically, the following lesions were present: A small posterior polar cataract, numerous fine vitreous opacities, and a horizontally oval optic disc of a greenish-gray color. The nerve-head was imbedded in the centre of a huge mass of opaque fibres which followed the course of the principal vessels almost to the periphery of the fundus and in all directions, but less decidedly downward and to the nasal side. A small patch in the macular region was not covered by the opaque fibres, but was disturbed by superficial choroidal changes. There was almost complete loss of the nasal field and of the entire centre of the visual field, with the exception of a small area to the nasal side of fixation, about ten degrees in diameter, within which the white test object was dimly seen. Colors were correctly appreciated when held in the temporal field. The case was illustrated by a water-color drawing made by Miss Washington.

In the discussion, Dr. B. ALEXANDER RANDALL showed a card-specimen of a case of retained nerve-sheaths in a case that had been sent to him for supposed intracranial disturbances. In this case there was an isolated patch situated in the macular region.

Dr. OLIVER exhibited the drawing of a case in which the medullation began at the edge of the disc and divided into two cometlike processes extending along the lines of the larger retinal vessels. This case had been seen through the courtesy of Dr. Goodman and Dr. Ziegler at the Wills Eye Hospital. He also spoke of a drawing that had been made for him by Dr. Randall, which was one of the most extensive of annular types that he had ever seen. The case occurred in a nine-year-old highly myopic boy who never had had any subjective symptoms of the condition.

**An Asbestos Cover-Chimney with Disc Attachment for Ophthalmoscopic Purposes.**—Dr. JAMES THORNTON, by invitation, exhibited this device. The original form with the disc attachment he had made two years previously. The present arrangement showed that five changes could be made in the disc. 1. The one-centimetre opening fulfilled all the purposes of the original chimney. 2. The two-centimetre opening permitted of greater freedom of movement on the part of the observer without moving the light. 3. The three-centimetre opening might be used as a source of light for the concave skiascope or for the ophthalmoscope, otoscope, etc. 4. A round section of cobalt-blue glass for the chromatic-aberration test of ametropia had been added, as also: 5. The perforated disc, with perforations and spaces each of 1.45 millimetre, to test for astigmatism at one metre's distance. The author stated that he had a new form of contrivance in the course of preparation, which would have a simple shutter with different changes in it, to work up and down in front

of the opening in the asbestos chimney by means of cogwheels. He should also employ a horizontal slip one eighth of an inch wide to exercise the oblique muscles, as suggested to him by Dr. Savage, of Nashville, Tenn.

Dr. CHARLES SHAFENER strongly recommended the asbestos form of chimney, as it radiated but little or no heat and was always sufficiently cool to handle without burning the fingers. It had been his intention to present one that he had been using for some time, but, as he considered that the present form and the one recently brought forward by Dr. M. W. Zimmerman were much better, he had refrained from so doing.

**New Perimetric Lenses.**—Dr. THORINGTON showed a new form of perimetric lenses which received their name from the fact that their optical centre corresponded to the points of fixation in the fields of vision. The reasons given for the recommendation of the lens were that it gave to the eye that form of lens which was consistent with a normal form of the visual field, it removed the edge of the lens to such a distance that the edge could not be seen to any great degree while the eye was fixed straight ahead, and bifocal segments could be made much larger. He stated that the increase in weight need rarely exceed the ordinary form of from twenty-five to thirty grains; the large size did not attract much attention; and the cost would remain the same as in the ordinary styles used. On account of the necessary great weight and thickness, he believed that this form of lens could not be used for cases of aphakia and high myopia, but showed that, as this class of cases constituted much less than one half of all refraction cases (thirty-seven per cent.), the lens would be accepted in the majority of instances.

**Microscopic Specimens showing the Various Forms of Eyes seen in Fish, Reptiles, Birds, Quadrupeds, and Man.**

—Dr. OLIVER exhibited and demonstrated a series of such specimens. He showed the marked differences in the conditions of the dioptric media, the varying shapes of the eyeball, the relative positions of the eye in the head of the animal, the adaptations for near-focusing and for far-focusing, the arrangements for increase of the interior illumination, the positions and peculiarities of the nerve structure, and the relationship existing intracranially between the two organs in the aquatic, the terrestrial, and the aerial forms of animal life.

## Miscellany.

**The Treatment of Tremor.**—In an article on this subject, published in the *Journal des praticiens* for August 29th, M. Liegeois recommends the following methods: In the trembling of sclerosis the motor-excitant medicaments tend rather to exaggerate the trouble; but its oscillations diminish perceptibly under the influence of solanine, which is preferable to potassium bromide, to belladonna, and even to acetanilide, according to Lepine, and to salol, which Dubief employed in amounts of from forty-five to ninety grains a day. The dose of solanine is from 1.5 to 4.5 grains a day. Cold douches and galvanic baths also diminish the trembling, and, according to Bernheim, suggestion does the same.

In hysterical trembling cold douches, cold baths, spraying with ether or with methyl chloride on the

spine, electro-static baths associated, if desired, with feeble mechanical excitation are, together with complete and systematic isolation, more useful than all the antispasmodic medicaments. Bromides especially must be avoided. Metallotherapy, magnets, suggestion, and rotating mirrors, according to Lays, are to be reserved for the rebellious cases, and ovarian compression for the paroxysmal trembling or for that which follows acute emotional shocks.

For the trembling of neurasthenia warm douches are recommended when the subject is arthritic; if not, they may be followed by cold douches or cold baths. Spraying with ether or with ethyl chloride on the spine, where the tender spots are usually found, is indicated in these cases rather than in hysterical subjects. Electricity in the form of Paul's galvanic baths or electro-static baths of feeble intensity may be used. Tonics are useful aids to the principal treatment.

The treatment of epileptic trembling does not differ from that of epilepsy itself, as the trembling does not manifest itself apart from the attacks, since it forms an integral part of the attacks, whether it replaces the tonic phase, whether it alternates with the clonic convulsions, or whether it follows a paroxysm of delirium; and of agitation in cases of established epilepsy.

The almost constant trembling of Basedow's disease does not demand intervention when it is slight; as soon as its rapid oscillations cause violent shaking of the arms, even when at rest, when the legs assume a pedal movement, tincture of veratrum must be administered in amounts of from ten to twelve drops a day during a period of weeks, or antipyrine in amounts of from thirty to ninety grains a day. Strong electro-static baths are also followed by the most favorable results.

In regard to the trembling of paralysis agitans, the author is undecided as to whether it should be combated by motor-excitants rather than by reflex sedatives or *vice versa*. The muscular rigidity, he says, and the partial contractures which are coincident with the trembling are sufficient indications that the Parkinsonian trembling belongs to the convulsive order; consequently it is not surprising that the motor-excitants exaggerate the trouble. The following reflex sedatives will be found to be useful in these cases: Alkaline bromides, from seventy-five to one hundred and eighty grains a day; camphor bromide, twenty-two grains; and sodium borate, from fifteen to forty-five grains; extract of belladonna, from 0.3 of a grain to three grains; hyoscyamine, from 0.0062 to 0.186 of a grain; this should be preferred to the extract of hyoscyamus and to daturine, the effects of which are too slow, and to hydrobromide of hyoscyamine or to sulphate of duboisine, which are dangerous to handle; veratrine in very minute doses, and better still, the tincture of veratrum viride; hot baths at a temperature of 122° F.; cold affusions on the head and applications of ice to the region of the fissure of Rolando; and Paul's galvanic baths or electro-static baths. The author thinks that subcutaneous injections of a four-per-cent. solution of sodium phosphate diminish the Parkinsonian trembling, and that they are more efficacious than arsenic. When the disease has evidently followed exposure to cold and wet, sodium salicylate or salol is recommended. The trembling which is cured by mercurial treatment and potassium iodide does not depend, the author thinks, upon paralysis agitans, but should be ranked in the category of syphilitic trembling, which is coincident in some neuropathic subjects with the appearance of

secondary symptoms. If cauterization of the nape of the neck and in the sacral region, if hypodermic injections of ergotinine have acted sometimes as reflex sedatives, it is by producing anæmia, directly or indirectly, of the spinal marrow that they have restrained the excessive activity of the anterior cornua. After the ingestion of a large dose of opium or of morphine for insomnia, the trembling increases, but with the use of codeine the results are different.

Nothing seems to give better results, says M. Liegeois, for senile trembling of the limbs accompanied with a transverse or vertical tossing of the head, than an analeptic diet and river bathing, if there are no contraindications; an infusion of the flowering heads of *Chenopodium ambrosioides* may also be given in the proportion of from one hundred and twenty to one hundred and fifty grains to a pint of water. Is it not possible, asks the author, that generalized faradization, Paul's galvanic baths, and electric baths may retard the evolution of the peripheral polyneuritis which appears to provoke senile trembling?

The inability of the hands to hold anything, the paresis of the legs, with a dragging gait, the arrest of the tendinous reflexes, and the trembling which are seen in alcoholics, should be classed, the author thinks, with the trembling of paralysis. In such cases strychnine alone is not so efficacious as when it is associated with picrotoxin and with veratrine. Ten galvanic or electric baths give successful results in tremor potatorum. For this acute stage of chronic alcoholism, which is called delirium tremens, alcohol in doses of from two to three ounces is an excellent remedy, which, says M. Liegeois, has never failed to give him good results. It induces sleep immediately and the patient awakens cured; whereas opium, chloral, methyal, and strychnine have failed to induce sleep under three or four hours.

Three kinds of trembling of metallic origin, from mercurial, lead, and copper poisoning, are amenable to the same treatment, that of potassium bromide in amounts of from thirty to one hundred and fifty grains a day during a period of a month. It forms with the metallic substances a soluble bromide of double strength which is easily eliminated by the urine. The trembling of those who work with rubber and arsenic is tenacious, and there are no eliminating agents for these poisons except friction and baths.

The trembling of inveterate smokers and of those who abuse the use of coffee, rarely of tea, ceases shortly after the suppression of these poisons.

The trembling due to the use of opium or morphine, to hasheesh, or to cocaine supervenes as soon as the subject is deprived of the poison, and it is difficult to overcome.

M. Liegeois calls attention to a rare form of trembling which disappeared after lumbar puncture had been practised. The patient was a woman who was attacked with the trembling a year after the onset of coccygodynia. She was not hysterical.

The author states that he has observed a permanent trembling of the hands, and especially of the thumb, in a woman who suffered from aortic insufficiency with visible capillary pulsation; a transmitted trembling which M. Liegeois thought was connected with the impact of the blood against the walls of the capillaries spasmodically closed, as is frequently the case in aortitis. The trembling became considerably modified under the influence of the tincture of veratrum viride.

which acted in this case as a brachycardiac and arterial depressor rather than as a reflex sedative. M. Liegeois thinks that the value of sparleine sulphate has been exaggerated in the treatment of the trembling of neurasthenia, of sclerosis *en plaques*, and of long-standing hemiplegia.

**The Serum Treatment in Grave Scarlatina.**—In the *Presse médicale* for August 26th M. Roger contributes a long article on this subject, of which the following is the substance: Scarlatina, he says, would be a comparatively benign disease, at least in adults, without the secondary manifestations which too often follow it. However, in spite of the frequency of otitis and nephritis and of the dangers to which these complications expose the patients, the mortality is not very high. Out of a hundred and eighty-three cases which came under M. Roger's observation during a period of six months, only two patients died. In one case the patient had secondary syphilis. The scarlatina was not very intense and recovery took place rapidly; the albumin disappeared on the tenth day and the patient seemed to be fully convalescent, when, on the twenty-eighth day, albumin was again found in the urine. The patient was put immediately on a milk diet, but on the following day she was taken suddenly with a terrible attack of suffocation and died in a few minutes. At the autopsy, besides the renal lesions, a subacute œdema of the lungs was found. It is very certain, M. Roger thinks that in this case death was not caused by the fever, but by the renal lesion which was provoked by the primary infection or by a secondary infection. In the other case death ensued after the eruptive period. When M. Roger saw the patient he prescribed cold baths and a subcutaneous saline injection, but before the treatment could be begun the patient died suddenly. At the autopsy the usual lesions of intense fever were found; the blood was fluid, black, diffuent, and badly coagulated; there was intense congestion of the viscera; the cortical substance of the kidneys was dotted with red spots, and the spleen was enormous. The bacteriological examination revealed the presence of streptococci in the blood and in the viscera. It seemed difficult, in spite of all this, says M. Roger, to attribute death to a secondary infection, for it was a true case of malignant scarlatina.

M. Roger gives a detailed account of another case in which he determined to use active therapeutic measures and procedures which had given successful results in other infectious diseases. The prognosis of the disease seemed to point to a rapidly fatal termination, and he resolved to make a trial of the serum treatment. The preparation for this occupied an hour, and during that time the patient's condition became worse, so that death seemed imminent. At eleven o'clock in the morning phlebotomy was practised on the patient, and afterward eighty cubic centimetres of defibrinated blood which was taken from a patient convalescent from scarlatina were injected under the skin of the abdomen. Five hours later the patient was sleeping quietly and breathing easily. When he awoke and moved the respiration changed and became of the Cheyne-Stokes type; the pulse was 120 and feeble; the tongue was moist; the temperature, however, remained high and no urine was passed. A bath of 82° F. was then given and the temperature began to fall. Three hours later twelve ounces and a half of saline solution were injected subcutaneously and in an hour urine was passed. Two hours later the patient was sleeping quietly; the pulse was 100, and the respiration 25.

On the following day the patient was completely changed; he felt better and asked for food; his tongue was raw but moist; the eruption was pale, except on the legs, where it was still very pronounced; the pulse was feeble but regular, with 80 pulsations; and the respiration was 22. During the twelve hours following the last injection the patient passed eleven hundred cubic centimetres of urine, which was of a dark-red color, but it contained no albumin. The temperature during the day ranged about 100.2° F. and on the following day it became normal. For several days afterward nothing special was noted, and the infection terminated rapidly. M. Roger says that he has never seen such a rapid recovery follow in such a grave case of scarlatina.

During the course of the disease the toxicity of the urine was demonstrated from day to day by intravenous injections in rabbits, all of which died in from twenty to thirty-six minutes after the experiments were begun; the symptoms manifested were convulsions, salivation, and excessive contraction of the pupils. M. Roger thinks it would be interesting to study the toxicity of the urine in scarlatina; the investigations, he says would be all the more important because, in the preceding observation, the evolution was absolutely anomalous. In this case defervescence was rapid instead of being progressive, as is usually the case, and the disease terminated suddenly. This, he thinks, is one of the best arguments in favor of the serum treatment.

It is not the author's intention to draw any conclusions from this case; he reports it simply to call attention to a method of treatment which may perhaps be of service and certainly deserves to be studied.

**Immediate Cystorrhaphy following Suprapubic Cystotomy.**—In the August number of the *Revue de chirurgie* there is an article by M. de Vlaccos, of Métélin, who deals only with immediate suture of the bladder after cystotomy for calculus, for it is especially in these cases, he says, that suture of the organ can nearly always be practised, as is shown by the rarity of the vesical alterations which investigation as to primary union may contraindicate.

Although immediate cystorrhaphy following suprapubic cystotomy was for a long time commonly employed by many foreign surgeons, says the author, in France this ideal treatment of the vesical wound was not adopted with enthusiasm, and even at the present time, in spite of the attempts and the success of Tédénat, J. Lucas-Championnière, Schwartz, Tuffier, S. Pozzi, Bazy, Ricard, Segond, and others, siphonage is the method which is generally employed and advocated by the chief of the Necker Hospital and his pupils, by C. Monod, P. Reclus, Desnos, and the majority of operators.

M. Vlaccos states that his personal observations of suprapubic cystotomy are not sufficiently numerous to serve as a basis for investigations as to the frequency of vesical alterations, but from a study of other observations he is led to consider that alterations of the organ profound enough to contraindicate suture are very rare. It seems to him, moreover, that even the advocates of suture are too much inclined to admit the existence of vesical lesions which contraindicate primary union. The author states that, in regard to extreme friability of the vesical walls, he does not see in the common vesical lesions in persons suffering from calculus any justifiable cause for proscribing immediate suture. Another argument, he says, which is advanced by the opponents of immediate union, is the difficulty of securing a good suture,

If the success of primary union depended on the perfect occlusion of the sutured wound, the advocates of immediate suture would without doubt cease to run after this illusion; for, according to the author, in spite of some assertions to the contrary, with no special skill on the part of the operator, with any kind of suture, absolute occlusion of the vesical wound can not be obtained. But, he asks, is it really indispensable that suture should be occlusive to such a degree? Evidently not, for, with all precaution taken, if the bladder is not at any time distended by urine in such a way as to cause the intersutural spaces to gape and allow the urine to filter into the prevesical region, what good is to be obtained by striving to seek a chimerical occlusion? An occlusion which is as exact as possible of the cut edges, with intermittent catheterism or a stationary sound which works perfectly, is sufficient to shorten the patient's stay in bed and to prevent all post-operative complications.

There are many procedures for suture, says M. Vlaccos, which are recommended by various operators, but the majority of them are useless. The two methods which seem to the author to be sufficient in practice are S. Pozzi's hem-stitch and Bagg's purse-string suture. The suture may be made with silk or with catgut. M. Vlaccos gives the preference to the latter; its absorbability is no reason, he says, for rejecting it.

The author states that he has practised cystorrhaphy at three periods of life. Old age has shown itself to be as favorable for the operation as infancy or middle life. He is convinced that immatulate bladders are not indispensable to immediate union, and he does not consider, with certain surgeons, that infancy is particularly propitious to the success of the suture. In all the cases in which he has practised suture he has allowed the patients to walk on the twelfth or fifteenth day; can as much be said, he asks, of those in whom siphonage is practised? The rapidity of recovery is in itself a very great advantage of cystorrhaphy, an advantage which the operator should always seek in practice, especially for the class of patients who have to work incessantly for a bare livelihood.

**The American Electrotherapeutic Association.**—The sixth annual meeting will be held in Boston, on September 29th and 30th, and October 1st, under the presidency of Dr. Robert Newman, of New York. The programme includes the following papers: The president's address—The Want of Education in Electrotherapeutics in Medical Colleges; What can be Done by the Use of Electricity to Avoid Surgical Operations? by Dr. G. Betton Massey, of Philadelphia; Electricity in Chronic Non-suppurative Affections of the Uterine Appendages, by Dr. F. Shavoir, of Stamford, Connecticut; Electricity in the Treatment of Diseases of the Throat and Nose, by Dr. O. B. Douglass, of New York; Electricity in the Treatment of Diseases of the Larynx, by Dr. W. C. Phillips, of New York; Accidents and Risks in the Use of Street Currents; how far are they Practicable and Safe in the Use of Electrotherapeutics? by Mr. J. J. Carty, E. E., of New York; Showing the Danger to Patients and to Operators, and the Utter Unreliability of Fuse Wires, Resistance Coils, and Incandescent Lamps as a Preventive of Excessive Flow of the Current into the Patient, by Mr. John J. Cabot, E. E., of Cincinnati; Experiments upon the Effects of Direct Electrization of the Stomach, by Dr. Max Einhorn, of New York; Electricity in Diseases of the Stomach, by Dr. David D. Stewart, of Philadelphia; The Static Current in the Post-apoplectic State,

by Dr. John Gerin, of Auburn, N. Y.; The Electrical Principles Generally Used in Medical Treatment, by Professor William L. Puffer, of Boston; The Relations of Physics to Physiology, by Professor A. E. Dolbear, of Somerville, Massachusetts; Electrotherapy in the Treatment of the Nervous, by Dr. W. S. Watson, of Fishkill-on-Hudson, N. Y.; The Role of Electricity in the Treatment of Uric-acid Diathesis, by Dr. J. G. Davis, of New York; Some Observations in Electrotherapeutics, by Dr. D. R. Brower, of Chicago; The Physics of the Production of the X Rays, by Mr. Edwin Houston, Ph. D., and Mr. A. E. Kennelly, F. R. A. S., of Philadelphia; The Treatment of Strictures by Electrolysis *versus* any other Treatment, by Dr. F. H. Wallace, of Boston; The Newman Method of Urethral Electrolysis—its Advantages, and the Reasons why Some Operators Fail, by Dr. Francis B. Bishop, of Washington, D. C.; Faradism in Gynæcology, by Dr. R. J. Nunn, of Savannah, Georgia; The Motor Dynamo Adapted to Electrotherapeutic Work—The Application of Electricity to Surgery, by Dr. William J. Herdman, of Ann Arbor, Michigan; A Summary of the Ultimate Results in Eighty-six Fibroid Tumors treated by the Apostoli Method, by Dr. G. Betton Massey, of Philadelphia; Some Experience and Experiments in the Construction of High-tension Coils and Electrodes, by Dr. Frank W. Ross, of Elmira, N. Y.; Electricity Considered in its Relation to Surgical Gynæcology, by Dr. O. S. Phelps, of New York; A Clinical Report of a Case of Rectal Phlebitis treated by Galvanism, by Dr. D. B. D. Beaver, of Reading, Pennsylvania; and the Electrotherapeutics of the Constant Current, by Mr. A. E. Kennelly, of Philadelphia. Other papers will be read by Dr. Frederick H. Morse, of Melrose, Massachusetts, and Dr. M. A. Cleaves, of New York.

**The Effects of the Poison of the Poison-bearing Fishes, *Trachinus Draco* and *Scorpaena Acropha*, on Man and on Animals.**—Dr. James Dunbar-Brunton contributes an interesting article on this subject to the *Lancet* for August 29th in which he gives a detailed description of these fishes and of the poison glands which serve as a mode of defense by causing the death of their enemies and preserving their own existence by making other fishes hesitate to touch them. The two fishes which Dr. Dunbar-Brunton deals with are very poisonous and are commonly found on the shores of the Mediterranean. They are only poisonous, he says, as a serpent is poisonous—that is, by wounding, for their flesh is good and wholesome. They differ greatly in appearance, but the poison produces the same effects. The effect of the poison on small animals is as follows:

A guinea-pig or rat being chosen for the subject of the experiment, one of these fish is grasped with a cloth and the spine is pressed against one of the animal's hind limbs till the point enters the skin. A few minutes after the animal has suffered this puncture from a recently caught living or dead fish it gives a few gasps and squeals, at the same time twitching the injured limb; these symptoms of local pain and irritation advance within a varying period to more general ones. This is the period when the poison is distributed throughout the system. Great pain is exhibited, and though when undisturbed the animal is affected with tremors, yet if excited at this time convulsive movements and contortions are produced, accompanied by screams of fear and pain. The animal finds itself unable to run or escape and often falls over, clawing the air with its fore legs; then, if left alone quietly, these

pass and the animal drags itself along by the front legs, the hind quarters being semi-paralyzed. Any touching or handling of the injured limb intensifies the sufferings of the animal. At this time the place of puncture is intensely red and swollen, and this area extends almost half an inch round the wound. All the wool is shed from the skin, which exudes a reddish serum. Later, if the animal is still living, this part is gangrenous. Usually, however, from now the progress of the poison is very rapid, and the animal is in a condition of semi-paralytic collapse. The pulse is small and the feet are cold. The urine and feces are passed involuntarily, the urine dribbling away. The eyes are starting and the nostrils distended, and respiration seems difficult. The animal is unable to move, the hind legs are stretched and flaccid, and almost completely paralyzed. This collapse becomes more profound and is soon followed by death. These symptoms and signs may be compressed into one hour or more, depending on the concentration of the poison injected. In cases where the poison is in very small quantity the animal may live for fourteen or sixteen hours before death comes.

To illustrate the effect of the poison on man, Dr. Dunbar-Brunton takes the case of a man who has been unfortunate enough to strike against one of these fishes with his foot. At the moment of puncture only the sharp prick is felt at the place of contact with the spine. In a few minutes, however, the part begins to burn and itch and then becomes acutely painful with sudden stabbing pains. These pains increase in violence and shoot from the foot, passing up the leg in lightning darts, which force the person to lie down and writhe. Then a feeling of suffocation is felt, also pain over the heart. From this time, those cries of anguish which can always be recognized as caused by the acutest torture and fear begin. These cries are continuous, and beads of sweat stand on his brow. The hand is put to the throat and heart, as if the action could relieve the feeling of suffocation, which now becomes stronger. Flashes of light pass before his eyes and the pulse is found to beat intermittently. The sufferer, moaning and imploring for aid, gradually seems to lose sight of the bystanders, and a delirium sets in where only the cries persist, accompanied by convulsions. This state may pass on to collapse and death, or may, after lasting for many hours, gradually subside, leaving a malaise which is very difficult to get rid of. In one case, says the author, in which a man had been poisoned in the same manner, this subsequent malaise persisted for nearly two months. During that time the man was under constant treatment, the shock having been so great; the wound on the foot at the same time was very reluctant to heal.

The local appearance of the injured part at this time, continued Dr. Dunbar-Brunton, is as follows: At the moment of puncture there is seen only a small hole in the skin, which may be pigmented by the membrane from the spine. This puncture does not bleed. Round the puncture is an area of about half an inch in diameter, where the skin seems whiter than the surrounding parts. Outside this is an area of redness more or less diffuse. A little later this redness encroaches on the white central part where the puncture is, and soon all is of the same color. Next the red increases in hue from light to dark and then from dark red to black. When this occurs there is considerable oedema and oozing from the wound, which now opens. This part in a day or two may become gangrenous and slough off, leaving an ir-

regular wound, or the gangrene may burrow to deeper parts and affect the joints. In some cases it becomes necessary to amputate the foot. The inflammation, even when much milder, is difficult to heal, and this, the author thinks, is due to the injury of the trophic nerves by the local action of the poison. In other cases boils and phlegmonous bullae appear on the affected limb, and this may be accompanied by a phlebitis. Describing the effect of this poison on man, P. Savitschenko says: "At the place of puncture, at the moment when the fish has wounded with the aid of one or more of the rays of the dorsal, caudal, or stomach fins, or with the spines which some fish have on the gill covering, there is produced a great pain which extends in rays around the place that has been punctured. At the same time the wounded person is subject to a sensation of fear and anguish, followed by a faint, which is preceded or accompanied by nausea and general collapse. The wound at the moment of puncture shows only the form of the spine which has produced it. . . . Its circumference, pale at first, reddens afterward, becoming more and more pronounced, finally engorged and black. The sick man at the same time is taken with a fever more or less strong, depending on the force of the wound and on the quantity and property of the injected poison in the skin, on the place and on the sensibility more or less of the person wounded. According to natives, these like wounds have often the most sad endings, the attention not being given in time or by incompetent persons."

The treatment of such cases, says Dr. Dunbar-Brunton, can be said to be twofold—to prevent the poison as much as possible from entering into the general circulation and to combat subsequent symptoms as they arise. If the wound is treated at once with a caustic or corrosive solution the major part of the general symptoms of poisoning may be averted or very much modified. Natives in the Mediterranean use bluestone for this purpose, but it is usually applied too late or insufficiently. The cautery, simple or galvanic, should be applied, or the wound well opened and washed with a strong solution of corrosive sublimate. The absorption of this poison is very rapid and the means at hand are generally the best to begin with. Thus it is better to open the wound and allow of free bleeding rather than wait for caustic or cautery. At the same time the patient must not be neglected. Brandy and sal volatile given frequently, as in snake poisoning, are of the greatest benefit. When there is much pain, morphine injections may be given, and these pains are among the most acute, so that quite a considerable amount of morphine will be required to alleviate these symptoms. Alcohol is valuable, as it also deadens the pains, and it may be given up to the semi-intoxication of the sufferer. The ammonia stimulates the heart against the effect of the poison. As soon as the acute pains are passed and the sufferer is more comfortable twenty grains of bromide of potassium with ten grains of bromide of ammonium may be given, combined with the liquor ammonii acetatis. This will give the patient a calm night and sleep. The subsequent treatment depends on the individual case. The malaise which follows lasts for a considerable time and is often complicated by the slow-healing wound in the foot or hand. In every case absolute rest should be enjoined.

The nature of this poison, says the author, approaches that of snake poison. It is alkaloidal, very quickly decomposed, and intensely rapid in its action. It is secreted by the fishes in larger quantities at the

spawning season and is most active in the male fish. It is a poison of which the smallest quantity introduced into the skin of an animal produces the greatest general effects, so much so that these fishes might well be called the snakes of the sea. The poison is clear, transparent, very slightly acid, and not at all viscid. It is forced into the canals of the spine only at the moment of use; at other times it lies in the gland. In any case it is secreted only in the smallest quantity, but this secretion goes on more rapidly in summer, when the spawning season is on hand. This animal-chemical alkaloidal poison, when introduced locally, produces within a few hours necrotic changes and a dead area follows. This is caused by its special action on the trophic nerves. Dr. Dunbar-Brunton thinks its special action seems to be on nerve tissue, as the general effects demonstrate, apart from local changes—pain, intense stabbing sensations, tremors, convulsions, and delirium. Then the heart is much inhibited, and this gives rise to feelings of suffocation and impending death. Dr. Dunbar-Brunton says that this alkaloid has not yet been isolated, but that if it should be done, it will be found to be more or less of the same group as the snake-poison alkaloids.

**The Action of Hot-air Baths in Albuminuria.**—The *Gazette hebdomadaire de médecine et de chirurgie* for August 27th publishes a report of a recent meeting of the Congrès français de médecine at which M. Carrié presented a paper on this subject. The author stated that he preferred this treatment to the use of vapor baths and to that of hot baths which did not produce sweating. The hot-air baths, he said, produced a sweating which relieved the kidneys by directing toward another tract a part of the substances which obstructed the kidneys and should be eliminated. Furthermore, the application of heat to the skin regulated the interchanges as all other excitants did, and patients with albuminuria were often subjects in whom combustion was deficient, or deviated from the normal type. The hot-air bath filled two principal indications: It relieved the kidney by the abundant sweating which it produced, and regulated the organic interchanges.

The immediate physiological effects of this treatment, said M. Carrié, showed themselves by a sensation of heat, which was not at all disagreeable, and an abundant sweating which was accompanied by an acceleration of the pulse and an elevation of temperature. Respiration was not at all affected. No symptom was produced, except some palpitation and headache during the first baths, which lasted about an hour; sweating was the only symptom that persisted for a greater length of time.

The therapeutic effects were manifested by the changes in the urine, the quantity of which diminished on the day after the bath, and a rather intense polyuria which supervened on the following day. The density of the urine was in inverse proportion to its quantity. The urea scarcely underwent any modification. The rate of albumin greatly diminished on the day after the bath, but it increased on the following days, although it did not return to the former quantity. Gradually, however, this diminution became persistent and finally there was complete disappearance of the albuminuria.

Hot-air baths, said the author, were indicated in cases of subacute and chronic nephritis in epithelial forms; they were, however, contraindicated in the vasculo-connective forms, and when arteriosclerosis, a skin disease, or a nervous condition existed.

## Lectures and Addresses.

### LECTURES ON ANGINA PECTORIS AND ALLIED STATES.\*

By WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

#### LECTURE V.—PSEUDO-ANGINA PECTORIS.

AN angina *notha*, false angina, was first described, so far as I can ascertain, by J. Latham in a paper (1812) on certain symptoms "usually, but not always, denoting angina pectoris." According to Huchard, the term pseudo-angina was introduced by Lartigne in 1846. Walshe called attention particularly to this condition, stating that "genuine angina pectoris is undoubtedly a very rare affection. On the other hand, I almost daily meet with a form of complaint combining, in a minor degree, many of the characters of angina; and to this imitation of the true disease I propose to give the name of pseudo-angina. I believe that herein lies the explanation of Laennec's notion (so discordant with the experience of English observers) that angina pectoris is of very frequent occurrence." The term which has come into general use, and is of no little value, has not passed without criticism. Balfour (*The Senile Heart*) says: "The term 'pseudo-angina' is often applied to anginous pains occurring before middle life, especially in the female sex, and yet we see that fatal angina may occur in one who is still but a girl. To talk of pseudo-angina is, however, a mark of ignorance rather than of refinement of diagnosis; for angina is but a symptom, and if well marked, it should no more be stigmatized as 'pseudo,' because it occurs in youth, than the lesion with which it is sometimes associated should be called functional because it happens to be curable." And yet, not two pages off, he says: "But in what we may term—for want of a better expression—false angina, we have only to deal with the pain, the danger of which depends upon its cause," and in reality he subsequently acknowledges the wisdom of Walshe's division.

Burney Yeo says: "I do not admit a pseudo-angina of some authors. Hysterical imitative anginas, however, certainly occur. But . . . there is simply a gradation of severity and curability between the so-called cases of pseudo-angina and those of true angina."

Morison, too, in a recent paper,† questions the correctness of the term: "A case of true angina is one in which there is no doubt about the angina, and there is no mistake about the reality of the pain or breast-pang in many so-called functional cases." "The idea of spurious angina is only permissible in so far as the angina is not associated with demonstrable lesion," and tends to

get well. Herein lies the essence of the whole matter—the symptoms, on the one hand, indicate the existence of a grave organic, usually incurable malady, and on the other, a condition very distressing, it is true, but rarely serious, and usually curable. The advantages in thus recognizing a functional group far outweigh any theoretical objections, and in a series of cases the forms are, with few exceptions, fairly well defined.

I have notes of some twenty cases of pseudo-angina pectoris, cases in which there were recurring paroxysms of severe, even agonizing cardiac pain, often with radiation. The absence of the mental element—*angor animi*—and the existence of collateral features, etiological or symptomatic, served to separate them from the forms I have previously considered.

I have only taken cases in which the seizures were paroxysmal and intense; if one counted all the slight cardiac disturbances in hysterical and neurasthenic patients as pseudo-angina, the list could be greatly extended.

At the outset let me emphasize three points of special significance:

*Firstly. Pseudo-angina is an affection of women.* You remember that in the series of organic or coronary angina there was only one woman—a mitral-valve case—the only instance of true angina that I have seen in a female. Of the twenty cases of pseudo-angina, twelve were in women. If we exclude two cases of tobacco angina, there were only six instances in males. In my series it was much more common in married women; there were only two girls, each aged twenty-two. We can say then that pseudo-angina is almost as much a special disorder of women as true angina is of men.

*Secondly. It occurs in younger persons.* The average age of the subjects of spurious angina is much lower than in the other form—thirty-eight years in my series, the extremes being twenty-two and sixty years, the latter a woman who had had attacks for twenty or more years.

*Thirdly. The patients do not die.* While fifteen of the subjects of true angina on my list are dead, every one of the twenty patients with pseudo-angina is alive; of several of the cases of true angina I have lost track.

Two main groups of functional angina may be recognized—the neurotic and the toxic.

**I. NEUROTIC.**—The cases in this group present a good many minor differences, either in the characters of the attack, or in the circumstances which favor its onset; and, based upon these, various subdivisions have been made. A majority of the patients are either hysterical or neurasthenic, or the features of the attack are of themselves distinctive of hysteria. In others the vasomotor phenomena are specially marked, while in a third set of cases the attacks appear to be excited reflexly, either by peripheral or visceral irritation.

At the risk of wearying you, I will read the histories

\* Delivered to the Post-graduate class, Johns Hopkins Hospital.

† *Edinburgh Hospital Reports*, vol. iii.

of a series of cases, from which you will get an idea of the varied features of the attacks. In every one of the first three cases the existence of genuine angina had been suspected, greatly to the distress of the patient or the relative. In the fourth the attacks were so anomalous that the presence of a tumor in the mediastinum was thought possible. An apprehension lest the true nature of the case should be overlooked is, naturally enough, the feeling uppermost in the mind of the attending physicians, whom to convince of the hopeful nature of the complaint I have sometimes found very difficult.

**CASE I.**—Mrs. X., aged thirty-eight years, consulted me on January 9, 1894, complaining of attacks of agonizing pain in the chest.

Her father died at sixty-seven years, of cancer of the stomach; her mother, of nephritis, at the same age. There are no nervous affections in the family.

At the age of six she had rheumatic fever, and at twenty-one rheumatic sciatica, which has returned once or twice, but not within the past ten years. She has been married sixteen years and has two children. Until about six years ago she was subject at times to fainting fits, which would come on without any definite cause. She had them almost from her childhood, and I can not get either from herself or from her husband any accurate information as to her behavior in these attacks, which are apparently quite transient, and not associated with convulsive movement, nor does she apparently always lose consciousness. She is a woman of a good deal of character and determination, and of executive skill, and does not give one the impression of being of a neurotic habit. She has always been able to do a great deal of walking and has not suffered specially with shortness of breath. Five years ago she had an attack of appendicitis, from which she recovered without operation. In the spring of 1893, when returning from Colorado, and after a good deal of mental worry, she had an attack of very severe pain in the chest. It came on after exertion and exposure to the wind in walking. The pain was of terrible severity, extended up the neck and down the arms; but she was able to move about in it and was a good deal excited. Since that attack she has been, at intervals, a little short of breath on exertion. She has had two of the severe attacks since; one last summer at the seaside, when walking on the sand, the other two months ago. Both of these were of great severity; the pain was agonizing; she became gray and cold and exhausted, and the skin was covered with a clammy perspiration. She states, too, that she had a sensation as though she could not live through it. One of these attacks was followed by a transient facial paralysis. Last August, for the first time in her life, she began to have headaches, which have recurred as often as two or three times a week. They are of the type of migraine, and come on with disturbance of vision; she sometimes sees figures and queer things; once she had hemianopia. The attacks prostrate her very much.

About the middle of December her feet and ankles began to swell, particularly at night. At first there was little or no pitting, but now they are sometimes swollen to the knees. The urine has been normal in quantity and without albumin or tube casts.

The patient was a well-nourished, healthy-looking woman; pulse 80, regular, without increase in tension, and the vessel was not sclerosed. The thyroid was not

enlarged, and there was no puffiness of the face or above the clavicles. The feet and ankles at the time of examination were not oedematous. The examination of the heart and other organs was entirely negative.

A hopeful prognosis was given in the case, based on the view that the attacks, though severe, were probably pseudo-angina. The occurrence of migraine, with which pseudo-anginal attacks may alternate, and the swelling of the feet without evidence of heart or renal disease, were corroborative features. I have heard of this case several times; she got better, and the painful heart attacks, when I last saw her husband, six months ago, had not recurred.

**CASE II.**—Mrs. F. R., aged forty-two years, seen April 9, 1894, complaining of attacks of agonizing pain in the chest.

Patient comes of a very nervous family, and one sister is in a lunatic asylum.

She was well and strong until two years ago; she has had five children, the youngest six years old. She has never had any special illnesses. She was not specially nervous as a young girl, and had no crying spells or hysterical attacks. Her domestic relations are congenial and satisfactory.

The present trouble began two years ago last February, when one morning she had an attack of severe pain in the chest. It began in the pit of the stomach, became most intense under the left breast, and extended round the shoulder. As she expressed it, she thought death had come. She got cold, broke out into a profuse perspiration, and during the attack was completely helpless. The attack lasted for about an hour and left her much prostrated. During the succeeding year she had about four attacks, each of great severity and identical in character. In the past year they have become more frequent; thus, she has had two in the past month. The last attack was on the 1st of April. She felt comfortable in the morning when she got up, but after breakfast felt a little drowsy and heavy, and lay down on the sofa. The attack came with the greatest rapidity and was so severe that she could not rise. The breath gets short; she feels a sensation of deathly coldness about the heart, and the chief pain is under the left breast. She can not move about, and when the pain is at its height she can not bear to be touched. As it comes on she loosens her clothing, but as the attack increases in severity she is quite beside herself, tosses about, and is, as she says, almost dead. She groans a great deal, and in some of them has cried out very loudly. Her husband, who is a traveler, has only seen her in two attacks, both of which came on with great suddenness. She got very cold, the face became pinched and drawn, at first a little congested, and then pale. Twice she vomited in the attack. The duration has been from a quarter of an hour to an hour. She has had to have morphine hypodermically on several occasions. After they pass away she feels miserable and is wretched for two or three days. Sometimes the whole body is sore after an attack.

She knew of no special circumstance apt to induce an attack. She was low-spirited at times and noticed that she has been a little despondent prior to their onset. She has not been short of breath on going upstairs or uphill; not more than might be expected in a stout woman. Exertion has never brought on the attack.

The patient was a large, stout, healthy looking woman. There was no arcus; the color was good; the tongue clean; the temporal arteries not sclerosed; pulse 84, readily compressed; the vessel wall was not sclerosed. There was slight throbbing in the vessels of the neck. Percussion was clear on manubrium. The cardiac dullness began on the fourth rib; both sounds were clear and loud on manubrium. At first right interspace there was a soft systolic murmur, and the aortic second sound was here a little accentuated. The first sound was loud and clear upon sternum; there was no murmur at the apex. There was no pain on firm pressure over manubrium or adjacent parts.

The soft bruit at the aortic area, and the accentuation of the second sound, made me a little suspicious of this case, though the general features of the attack were rather those of pseudo-angina. The subsequent history, as obtained from Dr. G. W. Norris and from her husband, on October 27, 1894, and July 7, 1895, shows that she steadily improved and the attacks have now ceased.

CASE III.—Mrs. B., aged thirty-three years, seen with Dr. Smith, of Havre-de-Grace, February 11, 1895, complaining of attacks of pain about the heart and shortness of breath.

Her mother died of apoplexy at sixty; her father had a hemiplegic attack two years ago.

The patient was healthy as a child. At her seventeenth year had nervous prostration with headaches. She has never had any fevers, and has not had chorea or rheumatism. She has been married for twelve years; has had three children; the youngest is between three and four years of age.

The symptoms of which she now complains began about two years and a half ago. During her last pregnancy she had acute nephritis, but after delivery the dropsy disappeared rapidly. Within about six months she began to have attacks of palpitation and pains about the heart. These are very apt to come on five or six days before the menstrual period. She has two grades of attacks: In the severer type she gets very cold in the hands and feet. The heart begins to throb; she has choking sensations in the neck, and a sense of pain and oppression in the region of the heart. The pains do not extend to the arms. The face gets flushed, sometimes very much congested. She becomes very nervous, and the pain is so intense that she requires morphine. The attacks come on at any time, but exercise, heavy work of any sort, and worry, have seemed the most common exciting causes. In the milder attacks she has a little shortness of breath, the face becomes flushed, and there is a sense of oppression about the heart. They often pass off if she takes a hot drink or a dose of Hoffmann's anodyne; she has never fainted. She has no dyspepsia, nor does she think that anything she eats ever brings on an attack. She has been exceedingly nervous and worried about her condition, particularly since a physician told her a year ago that she was liable to die suddenly. Up to a year ago she weighed only a hundred and fifteen pounds; she has rapidly increased in weight to a hundred and forty-three pounds. She was a healthy-looking woman of a florid complexion. She did not look of a nervous temperament. The pulse was good, 100 a minute, without increased tension; the arteries were not sclerotic. The condition of the heart was negative, the

aortic second sound was ringing and accentuated. The pupils were equal; she had no arcus senilis.

There seemed very little doubt that this was a pseudo-angina, and I reassured her upon the question of sudden death. I heard of this patient on July 13th and on December 30th. She has not had a severe attack since February; for a few months she had "threatenings," as she calls them; since July she has been quite well.

The following case is of interest from the intensity of the paroxysms and the hyperæsthesia of the left arm. She had been alarmed, too, by the serious view which had been taken of her condition:

CASE IV.—Miss C., aged twenty-two years, referred to me September 29, 1891, by Dr. Clark, of Skaneateles, complaining of remarkable attacks in the region of the heart.

The family history is good, and she has herself always enjoyed very good health. She is evidently a high-strung, nervous girl, who has studied hard. When quite young, about the twelfth year, she had for a time pain in the left side about the heart and sensations of coldness.

The present complaint has persisted for between two and three years. She describes a pain, more or less constant in the left front of the chest, which sometimes goes down the arm, which becomes numb. She says she is never without this pain, and that it sometimes keeps her from sleeping. Then she had sudden spells, in which she has a terrible sensation of spasm in the region of the heart, as though something had grasped her. It differs altogether from the other pain. In severe attacks it has lasted all night, and she has had to gasp for breath. She does not perspire. The left arm becomes numb, often tingles, and in severe attacks the numbness extends to the left leg. The left arm feels almost paralyzed and is tender, and she can not use it in the attacks. There may be headaches, but she is never sick at the stomach. She never has any special coldness of the extremities. She has only had four of these very severe paroxysms within the year. During them she takes chloroform and nitrite of amyl. They have never been brought on by exertion, and she has been able to play tennis quite actively. Excitement and emotion most frequently cause them.

The patient was evidently very neurotic. She had no heart disease, no increased tension, and no sclerosis of the vessels. An interesting feature was the great sensitiveness of the left hand and arm. She jumped at once when I touched the wrist in order to feel the pulse. The various forms of sensation in it were perfectly normal. Though sensitive to the touch, she feels it numb and heavy. The sensitiveness did not extend to the skin of the chest.

The condition had been the cause of a good deal of alarm to her friends, and a diagnosis had been made by one of her physicians of a tumor pressing in the region of the heart. She was given a very favorable prognosis.

I saw this patient for a few moments about a year ago. She had entirely recovered from her attacks and, though nervous, seemed very well.

(To be concluded.)

## Original Communications.

TUBERCULOUS INFECTION OF  
THE LYMPHOID TISSUE IN THE PHARYNX,  
WITH SOME REMARKS ON LARYNGEAL INFECTION.\*

By JONATHAN WRIGHT, M.D.,

BROOKLYN.

In making the few remarks which follow, I do so as a sort of addendum to the paper which I hastily prepared last year for the discussion on tuberculosis of the upper air-passages by this association.

You may remember that I quoted a short abstract of a paper by Dieulafoy, of Paris, upon the lymphoid tissues of the throat as a tuberculous manifestation. In reading the paper † itself since then I found that his experimental evidence consisted of the following facts: In sixty-one guinea-pigs, he inoculated the peritoneal cavity with palatal tonsils from apparently non-tuberculous children. Of these, eight, or a little less than one in eight, contracted tuberculosis. In thirty-five guinea-pigs he inoculated lymphoid tissue from the nasopharynx in the same way, and seven of them, or one in five, developed tuberculosis.

Lermoyez,‡ you will also remember, had previously reported two cases of tuberculosis following, and apparently dependent upon, operations for adenoids.

Dansac \* had also made examinations of tonsils and found, as he claimed, evidences of tuberculous infection.

Now, if enlarged tonsils are tuberculous manifestations either in the oropharynx or in the nasopharynx, or if any considerable number of them, as above appears, really contain any tuberculous foci, laryngologists should know of it. Certainly we have been familiar with these growths for a long enough time to observe them carefully, and every laryngologist's observation has been wide enough to convince him that there must certainly be some mistake in the assertion that any considerable number are more than simple hypertrophies of pre-existing lymphoid elements.

Several years ago Massei, of Naples, wrote to me inquiring if I had ever found the tubercle bacillus in the healthy nose, and asking me to make inquiry of other observers. A well-known physician of Brooklyn, a skilled bacteriologist, at that time told me that he had found tubercle bacilli in his own nose, after a prolonged stay in the phthisical wards of one of our hospitals. He was and still remains, after a lapse of five or six years, a perfectly healthy man. This communication I forwarded to Massei with the statement of my belief that the bacilli would not infrequently be found to exist under such conditions in healthy noses and throats. Sev-

eral years later, Strauss, in Paris, reported his examinations by which he showed that such is the fact. Massei has lately published an address,\* in which he says that inquiry among many laryngologists by a circular letter had elicited only a few answers, and in addition to my own, only one in the affirmative, from Liebermeister, to the question as to whether tubercle bacilli were found in healthy throats. This was in 1892, and Strauss's work was published in 1891. The investigations of Baumgarten, Sims Woodhead, Krickmann, and others prove pretty conclusively that the bacilli do get through the epithelium of the throat and into the cervical lymphatics in tuberculous subjects and in animals fed on tuberculous food. Were it not for clinical experience, therefore, and such investigations as those of Dr. Hodenpyl, it would seem extremely probable that the lymphoid tissues of the throat should contain tubercle. Dr. Hodenpyl † examined about two hundred sections for bacilli and found none, nor anything like tubercle in tonsils.

The matter standing thus, I determined to repeat some of Dieulafoy's experiments. On looking over the catalogue of the pathological specimens which I had examined microscopically in the last six or seven years, I found among them about sixty tonsils and adenoids. These had been hardened and stained in various ways and examined histologically with no special search for evidences of tuberculosis, but of the whole number, which must have consisted of several hundred sections, none had ever presented an appearance which had made me even think of tuberculous tissue. One or more slides from nearly all of these specimens had been preserved, and I again went over them for evidences of tubercle. Occasionally, in an area of recent inflammation of a tonsil a giant cell would be seen, but never perfectly typical. No "coagulation necrosis" or other evidence of tubercle could ever be found. These specimens had never been examined for bacilli, and most of them had been soaking so long in the alcohol that they would be useless for bacterial examinations. I took seven of the more recent celloidin blocks, however, and stained four sections from each for tubercle bacilli with Ziehl solution that was giving positive results with sputum and tuberculous tissue.

As the cases came into my clinics last winter for operation, tonsils and adenoids in unselected cases were cut out with sterile instruments. Half of each specimen was put in a sterile test tube, sometimes with and sometimes without sterilized water; and the other half was put in ten-percent. formalin for twenty-four hours, then in alcohol, ether, and celloidin, blocked, cut, and stained with Ziehl solution. The pieces in the sterilized tubes were sent to my friend Dr. W. H. Park, who put them into the peritoneal cavities and subcutaneous tissues of guinea-pigs. The number of these experiments was for

† *American Journal of the Medical Sciences*, March, 1891, p. 257.

facial tonsils five, for postnasal "adenoids" seven. Of this series of experiments and examinations all resulted negatively. No bacilli of tubercle were found in the sections and no tubercle developed in the guinea-pigs, though three died of septicæmia.

Of course these few experiments, twelve in all, and negative in result, are not presented to refute Dieulafoy's more extensive work; but even had I obtained any positive results in the animal experiments, I should not have been able to say that I escaped the criticism which Cornil offered to Dieulafoy's work. Bacilli in his cases might have existed in the crypts and on the surface of the tonsil and not in its structure. What I have said in regard to the presence of tubercle bacilli in normal respiratory passages adds force to this suggestion.

While these experiments were being carried on I was asked by Dr. Walter F. Chappell to see a case at the Manhattan Eye and Ear Hospital. He has kindly furnished me with a report of the history and a drawing of the clinical appearances in the case, taken from a paper read at the New York Academy of Medicine before the laryngological section, and published in the *New York Medical Journal* for September 19, 1896. On reference to his paper it will be noted that symptoms of tuberculosis of the nasopharynx followed within a week after operation for adenoids, the patient being exposed to infection by attendance on a sister dying of phthisis pulmonalis.

From the history, I am inclined to think that the patient already had a tuberculous focus in her nasopharynx at the time of the first operation. The supervention of the symptoms only a week afterward could hardly be attributed to primary tuberculous infection, as we do not get such a speedy reaction as this, even in guinea-pigs.

Dr. Chappell, however, I believe, is of the contrary opinion as regards this case. A piece of tissue was taken from the nasopharynx and given to me for examination, and upon it I was able to make the following report:

The specimen received from Dr. Chappell was a piece of tissue about ten millimetres in its long diameter and five millimetres in its short. Half of this was sent to Dr. W. H. Park, who inoculated two guinea-pigs with it. Dr. Park reports that one of the guinea-pigs died in twenty-one days of septicæmia, and showed in addition to this perfectly typical tubercle in the spleen and other organs, the tubercles containing bacilli. Four months later the second guinea-pig, which had presented signs of disease, was killed and found to be suffering from disseminated tuberculosis. The other half of the specimen was put in absolute alcohol, then in alcohol and ether, and imbedded in celloidin. Sections examined under a low power show a lymphoid tissue crowded with tubercle, presenting the picture shown in the plate (Fig. 1). Examined with higher power, the characteristic structure of tubercle with many giant cells may be seen, the areas of coagulation necrosis being shown as light

spots in the drawing. Sections were stained for tubercle bacilli. A few were found in two or three sections out of about forty examined. The bacilli were never more than one to a tubercle granulum, situated usually in the centre of it, and sometimes in a giant cell.

*Diagnosis.*—Miliary tuberculosis of lymphoid tissue.

Thus it will be seen that the methods used in the twelve unsuspected cases, with negative results, gave a positive result in a case that was clinically perfectly apparent.

I have had colored drawings made, and you will note in Fig. 1 the striking appearance of the miliary tubercle under the low power (A \*). I desire here to refer to a paper by Dr. Ricardo Botey in the *Archivos latinos de rinologia*, etc., December, 1895, on Two Cases of Amygdalar Hypertrophy with Larval Tuberculosis.

His experiences resembled my own very much. He had also found giant cells in the section of a tonsil, but thought of them only as an inflammatory manifestation. In nineteen other tonsils, especially examined for them, he found giant cells only in two, but never found the bacillus.

In two cases which he saw later he found the tubercle bacillus in tonsillar sections and got positive results by animal experiments, but in both these cases there was, to judge from the histories, ample evidence of pre-existing tuberculosis elsewhere. After this Botey inoculated ten guinea-pigs with tonsils from non-tuberculous cases and obtained negative results, except in one case which died of a pulmonary and splenic tuberculosis, but there was no tubercle at the site of inoculation. From his experiences he deduces the following conclusions:

"1. That there exist certain forms of amygdalar hypertrophy of a primary tuberculous character, impossible by simple inspection to distinguish from the common hypertrophy of those organs with which every one is familiar.

"2. This condition, which constitutes a kind of larval (*larvada*) tuberculosis in some cases and latent in others, is a serious menace to the organism and a danger for the future, more or less certain, according to circumstances.

"3. This larval tuberculosis of the tonsils is present, especially in adolescence, without the least pulmonary or intestinal lesion which would make us suspect the evil.

"4. In some rare cases it is possible to diagnosticate it in time, with the help of the microscope and of inoculations.

"5. It is probable that the majority of the cases of hypertrophic amygdalitis are not tuberculous, for although in our experiments there occurred ten per cent., nevertheless, we do not know the proportion of one to the other, and simple ocular inspection reveals nothing.

"6. This does not signify that all the cases of larval amygdalar tuberculosis, even supposing that they are diagnosticated opportunely, are surely followed by different cervical adenopathies, terminating in a pulmonary

phthisis. On the contrary, it is probable that in many cases everything subsides into ganglionic infarcts without the tubercular germs reaching later the pulmonary parenchyma," etc.

As for my own impressions in this matter: In spite of the recent evidence here presented, I am inclined, both from clinical and pathological evidence, to agree with Dr. Hochenpfl when he says that tuberculous amygdalitis is a rare affection, and that the tonsils are rarely the seat of primary inoculation.

Considering the chances of primary, and especially of secondary infection, it certainly is rather remarkable that these structures should escape so constantly as they do. Moreover, tubercle bacilli have been found in the bronchial and mesenteric glands of apparently non-tuberculous people. They have been shown to exist in these lymphatic structures by animal inoculation when they could not be demonstrated by the microscope. That the same thing should be demonstrated in tonsils should not be a matter for surprise, but we should expect it to occur more frequently than appears.

I want to take this opportunity of presenting a drawing of a section which is more directly connected with the subject of tubercular invasion of the larynx than of the lymphoid tissues, and I have had a colored drawing made on stone for the same plate as the drawing of the tuberculous lymphoid structure.

The question of tubercle bacilli penetrating through epithelial structures has frequently been discussed, and very frequently such penetration has been denied. Last fall, in examining sections from papillomatous tissue removed from a tubercular larynx in a patient far advanced in pulmonary and laryngeal phthisis, I met with the picture, which you see reproduced on the plate in Fig. 2.

You will note that a veritable stream of tubercle bacilli is pouring into and through the thickened, squamous epithelial covering of the laryngeal mucous membrane. The epithelial cells are swollen and cloudy. The evidence of the penetration of tubercle bacilli through epithelial cells is here perfectly apparent. It is said by Lake\* and others that pyogenic cocci first create shallow ulcers through which the tubercle bacillus finds its way. This would appear not to be the case in this specimen.

As to whether the tubercle bacillus can penetrate the normal laryngeal epithelium of a healthy individual, it may still be considered a matter of some doubt.

This laryngeal case of mine ran the ordinary course of pulmonary and laryngeal tuberculosis, and terminated fatally, I should think, in about nine months. The case of Dr. Chappell's was more rapid, terminating in less than six months with general tuberculosis.

In the latter case the lymphoid tissue contained so few bacilli, notwithstanding the large amount of tubercle, that it required prolonged search through many sections to find even one. The enormous number in the epithelium from the larynx made a striking contrast.

It is impossible at present to explain the difference. The results produced by the infecting organisms in the two cases bear no proportion to their numbers, and this fact is a good one to bear in mind in watching the results of the researches into the real etiology of tuberculous infection.

## UNRESOLVED AMYGDALITIS.\*

By HOWARD S. STRAIGHT, A. M., M. D.,

CLEVELAND, OHIO.

CASE I.—Five years ago, when in general practice, I was called to see a boy aged ten years, sick with an acute follicular amygdalitis of the left tonsil only. There seemed to be nothing unusual in the case in any way. Aconite and acetanilide and a chlorate-of-potassium gargle were prescribed. A second visit was made twenty-four hours later. At the second visit the case seemed to be progressing favorably, and the next visit was made two days later. When seen the third time the left tonsil was still inflamed and swollen, but the more acute symptoms had passed away. Knowing that the family considered further visits unnecessary, I advised the continuation of a little quinine for a few days, and also requested that I should be notified if he did not progress favorably. Four days later I was again summoned. The swelling and tenderness of the throat had not pursued the ordinary course. At 1 p. m. his temperature was 100° F. and pulse 108. The swelling of the left tonsil was much more marked than it had been at any time during the first four days of his illness. The appearances suggested possibly a circumtonsillar inflammation with or without an accumulation of pus. The tenderness upon swallowing was marked. He had not been able to take anything but liquid food since the beginning of the illness.

A digital examination revealed no fluctuation, but a marked induration of the tonsil and circumtonsillar tissue, extending even to the tissues of the hard palate on the left side. I examined the boy's chest and found at his right apex a localized capillary bronchitis—an apex catarrh. He was given drop doses of creosote every hour, and all other treatment discontinued. In one day his throat was very greatly improved; all the symptoms of the local condition from this time passed away like snow in the sun. For a number of weeks I kept him under observation. The diagnosis as to the condition of the right apex was correct. After taking his creosote and tonics for a few weeks his parents considered him well, and discontinued treatment. After a few weeks he returned and after re-examining his chest and finding the same conditions still present he was put back again upon the former line of treatment. The boy slowly recovered from the constitutional condition, the local manifestation of which was the slight catarrhal condition at the right apex.

CASE II.—On February 15, 1896, a sewing girl, aged twenty-one years, consulted me as to her throat. She had markedly enlarged tonsils and adenoid growths. Her pulse was normal, and there was nothing in her history to cause suspicion of any necessity for constitutional treatment. The tonsils were removed by excision upon Saturday night and the girl was instructed to remain quietly at home until the following Monday. The next Saturday the adenoids were removed, and the

\* *American Journal of the Medical Sciences*, 1895, i, civ, p. 107.

\* Read before the Northern Ohio Medical Society, July 8, 1896.

patient again confined to the house for thirty-six hours. I saw her a few times only. Within a month of the time of coming under observation she was discharged. All this time I had no suspicion that the patient needed any constitutional treatment. Four weeks ago the patient presented herself, complaining of her left tonsil. Her pulse was about 100. Her temperature was not taken.

Her right tonsil showed nothing. The pharynx was also normal. The stump of the left tonsil was slightly swollen and a little reddened, but the change from the normal was so slight that I considered it merely the slight irritation of the tonsil that occurs so often as a part of an acute cold, and is of too little importance to call an amygdalitis. The patient made a good deal of complaint, but as she is a querulous, ignorant girl, and the throat showed almost nothing, I failed to realize the real extent of her suffering. I gave her one-tenth-grain doses of calomel every two hours, and suggested that she return in twenty-four hours. One day later she returned. She complained as much as ever, although there was little change in the condition of the left tonsil. I then gave her some sodium salicylate every two hours and discontinued the calomel. In two days she returned. The patient complained more than at any time thus far, and the swelling and redness of the tonsil were more marked than before. At this visit the sodium salicylate was continued, and the patient was directed to use an application of very hot water to the tonsil, according to the method of Dr. Charles W. Smith, of Cleveland. The method consists of rolling a large mass of cotton on a heavy probe, and, after dipping the cotton in water as hot as can be borne, in applying the heat directly to the tonsil. For two days she remained at home, for up to this time she had continued her ordinary work, and applied the hot water to her throat. At the end of this time—that is, five days after her first visit—she returned. Her throat was still in much the same condition as when the first and second visits were made, but was much better than two days before. I now gave her a placebo, and told her that the tenderness and swelling of the tonsils would soon pass away. In three weeks she returned. She said that the swelling and tenderness had never left her throat, and that she had been unable to take much food, except liquids. An examination of her throat revealed the left tonsil still swollen and reddened—a little more markedly than when last seen. I now awoke to the fact that this simple sore throat was pursuing a very different course from the ordinary. Her temperature was 99.6°, her pulse was 84. I sought an explanation of her case in the chest and found a slight catarrhal condition at each apex, and upon each side in the lower portion of the infralavicular region. I now gave her three minims of beechwood creosote, four times a day, and a thirtieth of a grain of strychnine sulphate. Within four days the tenderness and swelling had entirely disappeared. Under this treatment the tonsil was much improved in twenty-four hours.

The boy (Case I) was apparently a healthy little fellow. Apex catarrh occurs in children as young as this patient, though not so frequently as in older children or patients in middle life. There was nothing in this case to excite any suspicion of any such constitutional condition. The inflammation of the tonsil up to the time when I ceased calling at the house was in no way different from what one would expect in such a case. For the next

four days the course of the disease was altogether anomalous, and only explained by the condition of the chest, from which the child had been suffering, it may be, for weeks before the onset of the acute amygdalitis.

When this patient (Case II) first visited me I believed I was dealing with a simple follicular amygdalitis in a healthy person. I had no idea as to whether the slight inflammatory condition present in the left tonsil would remain stationary, progress, or recede promptly. Any one of these possibilities may occur. If treatment has anything to do with arresting further spread of the disease, or possible occurrence of the same inflammatory condition in the other tonsil, I am unaware of the fact. I have no objection to the use of sodium salicylate, and I use this remedy oftener than any other; and yet, whether cases do better on salicylates than they do upon aconite or vertrum viride or calomel or nothing at all, I have my grave doubts. I confess to a great skepticism as to the real value of anything in acute follicular amygdalitis in healthy patients. The time element seems to me to be all-important, and there is little to do that is absolutely essential for a few days except to relieve in so far as is possible the sufferings of a patient by means of anodynes, coal-tar products, or hot or cold applications. I gave small doses of calomel and awaited developments. It certainly could do no harm to attempt to re-establish the secretions of the body in an acute cold. At the second visit, thinking she had had calomel enough, and also taking into account the possibility of a rheumatic influence in simple sore throat, I gave her sodium salicylate. If rheumatism has any special influence in such cases I have never yet been able to demonstrate the fact to my satisfaction. Little importance was attached to the fact that the throat was no better, or possibly a little worse, than when first seen. On the third visit, at which time the throat was worse than at any previous time, I thought that in this case the disease was progressive and that the worst stage had been reached. The hot water was ordered, first, because I believed it to be a wise measure and also to gain time, for I confidently expected all symptoms to subside in a day or two. Her improvement at the fourth visit must have been due to the use of the hot water, although the tonsil had not returned to the normal at this visit. What other possibility could one reasonably expect in a short time? The placebo was given to satisfy the patient for a few days longer, as time was considered the all-important factor in her recovery.

In the first case, non-resolution of the tonsillar inflammation was the marked feature. I question whether if a localized capillary bronchitis had been suspected, and the case examined early, a positive diagnosis as to the condition of his right apex could have been made. The diagnosis of an early apex catarrh is difficult enough in adults, but much more difficult in children. Any acute trouble, with rapidity of pulse and fever and increase in the rapidity of respiration, makes

the diagnosis still more difficult. The earliest physical sign in apex catarrh—transfer of heart sounds—may be easily overlooked in a child, or considered to be due to overaction of the heart. The next earliest physical signs are rough and irregular breathing. Rough breathing occurs normally in children, and whether this normal condition is slightly exaggerated or not is not easy to decide. The localized irregularity of respiration, so important in adults, is also much more difficult of positive detection in a child. A positive diagnosis is often impossible. If in doubt, a little benzosal can be given, and the child watched until a positive diagnosis can be made. The history also, so important in adults, in the majority of cases is not equally helpful in children. As a rule, the disease seems to be more acute in onset and more rapid in recovery in children than in adults. As long as a child plays and has a fair appetite his condition excites no attention. The whims of childhood are so many and so like the early symptoms of a developing apex catarrh—irritability of temper, slight gastro-intestinal disturbance, fitful appetite, and drowsiness—that little is thought of his condition. Sometimes the mother can remember that some of the symptoms enumerated were observed. If it is possible to obtain any history as to the child's condition before the onset of whatever acute disturbance occurs for which the physician is summoned, the mother is most apt to remember that the child's appetite was not so good as usual or that he played less than usual. The feature of non-resolution was also pronounced in the second case. While the disease was less acute in onset than the first, although in appearance and course exactly like many a case of acute follicular amygdalitis up to the time of dismissal, resolution failed to occur when ordinarily expected. The subjective symptoms of the patient were also out of all proportion to anything that could be detected in the local lesion. An explanation of this fact was thought to be the patient's querulousness. The history in this case was all-important. Had it occurred to me that an abnormal constitutional condition was present, my suspicions would have at once been aroused. The course of the disease was so much like the ordinary that I was completely blinded. The general appearance of the patient contributed not a little to allaying a suspicion I always entertain in a patient in middle life who consults me as to a disease of the ear or upper air-passages. She looked well and her color was good. She showed no more gastro-intestinal disturbance than one would expect from her acute trouble. Upon close questioning, when she returned three weeks after being discharged as cured (?) from the acute amygdalitis, she told me that before the onset of the acute trouble she had felt very much tired out and that she had lost a few pounds of flesh within the last three months. If these two facts had been ascertained when she first presented herself complaining of her tonsil, my suspicions as to her chest would have at once entered my mind. Had I at this

first visit prescribed benzosal or creosote or guaiacol for her, and overlooked entirely any treatment for the tonsil, I would have saved the patient three weeks of suffering and myself a deserved humiliation. If I had the reputation of giving little thought to the importance of apex catarrh in diseases of the ear and upper air-passages, if I had not insisted in season and out of season upon the importance of this constitutional condition in Cleveland at least, any such error on my part could be more easily explained. As to the pathology in a case of this kind I have little to say, for it seems to me that the pathological process is no different from what it is in acute follicular amygdalitis in a healthy patient, but that for some reason the products of inflammation fail to be absorbed. I am equally at a loss to explain the wonderful improvement that occurs as soon as the patient is given some form of creosote. I do not wish it to be understood that every case of acute follicular amygdalitis in a patient suffering from apex catarrh pursues such a course as the cases reported. A certain proportion do pursue the anomalous course referred to, and they are difficult to understand if studied from the local standpoint only. The treatment early in the course of the disease need be no different than in the ordinary case, and yet the giving of benzosal in small doses could do no harm if there is any suspicion of a localized bronchitis. Neither could any harm result from the administration of benzosal if, after treatment with the ordinary remedies for a few days, the tonsillar inflammation fails to pass away. By so doing, the patient is given the benefit of doubt in any event. If, after acute follicular amygdalitis in which benzosal is given on the suspicion that it was necessary, the patient's temperature and pulse are carefully observed and an examination of the chest is made and nothing found, the remedy can be discontinued. In such a case it was as good as any remedy with which I am acquainted. On the other hand, if a localized bronchitis is found, the best possible remedy, in my opinion, has been administered. The purpose of my paper has been accomplished if the necessity for a careful examination of the chest in cases of unresolved amygdalitis has been impressed upon you, and, indeed, in any disease of the ear or upper air-passages.

THE HICKOX.

## A NEW METHOD OF TREATING INCOMPLETE ABORTION.

By ANNA M. STUART, M.D.,

BUFFALO, N. Y.

ONE of the most trying offices which the general practitioner is called upon to perform is the treatment of incomplete abortion. Self-induced abortion is frightfully common among the lower classes of the community, the same woman repeating the crime year after year. Since, according to the traditions of the laity, any interference is safe at the period of two months, they

task their ingenuity to perform barbarous operations upon themselves at this time. The male rubber catheter, a sharp trocar, a corset steel, a crochet needle, are all instruments thought safe enough to introduce within the uterine cavity. If "nothing comes," the operation is repeated day after day. And what is most surprising to the physician who has been brought up with a just dread of all dirty instruments on all occasions is that spontaneous recovery is the rule, and that the majority of cases never come under surgical care, unless for chronic pelvic diseases, which invariably follow such abuses.

But, occasionally, domestic surgery makes a failure, and delivery is incomplete. The uterus is inert and refuses to expel the secundines, bleeding continues, and the woman becomes frightened by the chills, fever, and vomiting. Then, and not until then, she seeks medical aid. She wants help, but she does not want to confess her part in the affair, and only most skillful questioning will succeed in drawing it from her. Even then she will falsify the history most tryingly in some detail. She wants relief as speedily and as quietly as possible, and she is often unable to go to a hospital or a specialist.

It adds much to the safety of the physician's reputation if the woman can be induced to explain the matter to her husband or some other member of her family before any treatment is undertaken.

I have been employing a method in these simple cases which seems rational, and is ordinarily safe to try for the first twelve hours. If successful, it is much easier both for physician and patient than the full dilatation of the cervical canal and the manual extraction of secundines with finger, curette, or placenta forceps. Moreover, it can be performed without disturbance in the household, without family assistants, and without anaesthesia.

I always bring a medical friend, but the work could be done single-handed.

The woman is placed crosswise of the bed (made as hard as possible) in dorsal position on a Kelly cushion. The external parts and vagina are thoroughly washed with green soap and warm water, and the hair trimmed off. This is followed by an antiseptic vaginal douche. The bivalve speculum, freshly boiled, is inserted and opened, and the screws are set. The internal os is usually patulous enough to admit Bozeman's intra-uterine douche. Through this a hot creolin solution is allowed to flow, always watching to see that the return current remains free. Then all loose clots and *débris* are removed by the dull curette. The cavity is again washed, and this process is repeated until nothing remains but the firm decidua tissue, which clings to the uterine wall and could not be removed without much dilatation, causing much pain to the patient. The hot creolin solution is an excellent hæmostatic, and is allowed to flow until it returns white.

Finally, the uterus is packed from the fundus to the external os with iodoform gauze prepared by myself. It contains more iodoform and more sterilized glycerin than the commercial article. The first gauze is withdrawn, thereby wiping out the cavity, and a second piece is firmly placed so as to stop all hæmorrhage.

The patient will usually endure this treatment without a groan. She is now put back to bed and given quinine, strychnine, and sometimes repeated doses of ergot. If pains come, she is told to endure them, and no opiate is allowed.

Now, what happens is this: The inert uterus is stimulated to contract. The blood, unable to escape, distends the cavity and flows in between the decidua and the uterine wall, dislodging the former. Finally, the internal os dilates, the gauze is expelled, and with it all the uterine contents.

Another creolin intra-uterine douche, and if endometritis exists the gentle use of the sharp curette and a gauze drain, complete the work.

Contraction and involution of the uterus go on rapidly.

**CASE I. Spontaneous Abortion.**—Mrs. S., aged twenty-six years; one child, aged fifteen months; menstruated three months ago, while nursing; had been suffering for a month with irregular discharge, pallor, and cachexia; was suddenly taken with chills and nausea. Temperature, 100°.

The uterine cavity was washed and packed as detailed above. A small hypodermic of morphine was first given to quiet her. The work was done in the evening. She slept well all night. In the morning a few pains came on, the gauze was found expelled, in company with a firm, round decidua in the vagina. Five days later a foetid discharge was noticed. Although the woman was feeling well, with temperature and pulse normal, the speculum was again inserted.

The rather large cervix was found filled with putrefying blood clots. These were removed, the uterine cavity thoroughly but gently curetted, and a gauze drain left in.

If the gauze had been put in after the first was expelled, I think the accumulation of blood clots would have been avoided.

Recovery was rapid, the gauze was expelled in thirty-six hours, and all discharge ceased.

**CASE II.**—Mrs. H., aged twenty-three years, no children; had had an abortion performed a year ago by a doctor on account of retroflexion with adhesions. Had been ill five days; admitted committing abortion by means of a crochet needle, repeatedly introduced; severe rigors; temperature, 104°. She was treated in the same manner. Her uterus was packed; contraction pains came on, accompanied by rigor, feeble pulse, and numb extremities. Stimulants were given, a reaction followed, and temperature rose to 106°; pulse, 120. Temperature fell during the afternoon slowly to 101°. Contraction pains continued, with more or less respite, for eight hours. Then gauze was expelled and decidua found lodged in the cervix, so as to be easily removed with the dressing forceps. Bleeding and pain ceased, and temperature was normal on third day. Rapid recovery.

In contrast to the foregoing I give the following:

CASE III.—Mrs. L., aged thirty-two years, three children; one previous self-induced abortion. Said she had passed two menstrual periods, had had chills and vomiting for two days. Temperature, 102°. Confessed to inserting some sort of instrument.

She was placed on a table in Sims's position, the internal os was freely dilated with much pain, and finger, douche, and curette were used to remove the uterine contents. The cavity, finally supposed empty, was washed and packed with gauze. Pain continued, and the next morning I was called on account of hæmorrhage, which was most alarming to the patient and friends, though not really serious. The gauze was found expelled and an overlooked piece of decidua tissue lodged in the cervix. When this was removed bleeding ceased. Recovery and involution of the uterus were slow.

This case, of course, shows failure in the first operation, but it also demonstrates the value of the gauze packing to bring on uterine contractions and the expulsion of the remaining contents.

The hæmorrhage was due to forcible dilatation of the os and rough handling of the soft uterus, together with failure to remove the entire contents.

#### THE SEQUELÆ OF SYPHILIS IN THE PHARYNX AND THEIR TREATMENT.\*

By J. E. H. NICHOLS, M. D.

WHILE, as a rule, the tertiary manifestations of syphilis in the pharynx heal kindly under treatment by mercury and the iodides, there is a proportion of cases in which the results of the disease are most persistent and annoying. We find changes in the soft palate, the uvula, the fauces, the posterior pharyngeal wall, the tonsils, and the epiglottis.

The destruction of tonsillar tissue can be very extensive without leaving any results detrimental to the patient, because its situation permits such destruction. The lingual tonsil, of the same tissue as the palatal tonsils, and subject to the same laws, has also been observed by Labit (*Revue de laryngologie*, 1891), Moure, Raulin, and others, to be the seat of syphilitic lesions, but, like its fellows, has yielded readily to treatment without any annoying results. No cases are reported in which distortions or obstructions either to deglutition or articulation have been observed.

The uvula is frequently subject to extensive ulceration, and may even be entirely destroyed without impairing the efficiency of the pharynx.

Perforations of the soft palate and the faucial pillars are not uncommon. These are of a more serious character on account of their interference with proper articulation and the discomfort caused by the regurgitation of

liquids into the nasopharyngeal cavity. I have recently seen a man of forty-five, a master mason, whose occupation requires him to call in a loud voice from the upper floors of buildings to the workmen below. His initial lesion took place twelve years ago. Four years ago, following a period of debility, a perforation of large size occurred in the right side of the soft palate, extending down into the posterior faucial pillar. The perforation was oval in shape, with its long diameter parallel with that of the pillar, and about two centimetres in length. His articulation was so indistinct, in consequence of the escape of air into the nasopharynx, that he could not be understood by his men, and he was obliged to give up his place and work as a day laborer. The edges of the opening were pared, under cocaine, and brought together by wire sutures. Perfect closure followed, and the man has been able to obtain his former position.

Ulcerations and malformations of the epiglottis resulting from syphilis are more common, but, unless excessive, are not of great importance. The entire epiglottis may be destroyed without serious inconvenience to the patient, because of the tolerance acquired to its absence. Occasionally the ulceration has been in such a situation that an adhesion between one side of the epiglottis and the interior faucial pillar ensues, causing a partial stenosis of the larynx. Such a case is now under treatment, in which the base of the tongue and the epiglottis are drawn upward and backward, causing considerable difficulty in articulation by limiting the motion of the tongue.

The most annoying sequel to syphilis in the pharynx is the formation of adhesions between the posterior faucial pillars, the posterior edge of the soft palate, and the wall of the pharynx, causing a partial or complete stenosis of the rhinopharynx. Extensive and coincident ulcerations of these parts are common, and when the subject is not placed under thorough iodism contractions are apt to follow on account of the approximation of the two surfaces at an acute angle. Internal medication is of more value in bringing about resolution than strong topical applications. Several cases observed lead to the belief that if the powerful caustic applications used had been withheld, and bland washes employed, no adhesion, or at least less extensive adhesions, would have followed. In one case pure nitric acid was used by the attending physician, with the result of setting up a deep submucous inflammation and a complete stenosis.

The discomforts of such formations are very great. Nasal breathing is entirely abolished and mouth-breathing substituted, with its sequelæ of dryness, laryngeal irritation, and pulmonary complications.

The voice is seriously affected, its resonance abolished, and its unpleasant, stuffy quality rendered most annoying to the patient and those with whom he comes in contact conversationally. Furthermore, the traction exerted by these cicatricial formations on the orifices of the Eustachian tubes and the disturbance of the equilib-

\* Read before the American Laryngological Association at its eighteenth annual congress.

rium of air pressure in the nasopharynx bring on most unpleasant aural complications, to which must be added the danger of acute catarrhal infection from the dammed-up secretions of the curtain. Again, the expiratory air current being shut off, the nasal secretions accumulate in the form of tenacious masses of muco-pus, which the patient can not expel except by gravitation and the use of cotton swabs or intranasal douches. There being no inspiratory current of air, the sense of smell is impaired or abolished, and all the proper functions of the nose are rendered useless.

In the treatment of these adhesions great ingenuity has been exercised in trying to find some surgical method which would produce a permanent opening. In the great majority of cases no success was had, the openings made closing by contraction after a period of time varying from a few weeks to two years.

Labit says "it must be frankly acknowledged that no means has been yet found which will afford permanent relief." Mackenzie says "though great relief can be afforded to the patient as long as he remains under treatment, no cure can be predicted, as the stenosis always returns when mechanical measures are suspended." Scheck says that "the results, as regards improvement and restoration of speech, are generally very unsatisfactory." These opinions are shared by Cartaz, Lichtwitz, Hajek, and other recent writers who have reviewed the subject.

A short recapitulation of the means which have been used will be useful. Elsberg separated the parts by means of a blunt-pointed staphylorrhaphy knife, forcibly dilated with the finger, and had the patient use daily a hard-rubber palate retractor to prevent readhesion.

Dieffenbach, after incision, drew the soft palate forward as far as possible by means of a ligature passing out of the mouth and fastened to the ears. Others, after incision, inserted tubes or rings of lead, metal, or rubber of appropriate shape and size, kept in position by being suspended from two strings passed through the nostrils, or by spring clips fastened to the teeth, or by suction in the roof of the mouth, as in case of a dental plate. Others have used sponge tents, hard and soft brushes, air bags, etc., while others yet have striven to do plastic operations of various kinds. At the present time these measures have largely given way to the repeated use of the galvano-cautery knife and subsequent digital or mechanical dilatation.

Lichtwitz reports a case of the last-mentioned method (*Ann. des mal. d'oreille*, 1894, 815) in which he was able to keep the passages open by constant dilatation with a No. 30 F. bougie.

Conetox (*Ann. des mal. d'oreille*, 1893) and Kuhn (*ibid.*, 1892) have introduced a method by which a large opening is made through the soft palate just behind the osseous palate and anterior to the uvula. In this opening is introduced what they term a "plaque à cheminée," which holds itself in place by the contraction of the

edges of the opening, and allows nasal breathing. This appears to be the best mechanical device yet found for overcoming the closure.

But all these operations and practices have one defect in common, fatal to their success, and which allows the reproduction of the original method of the adhesion. The defect is that no matter how deep the incision has been made, or how much tissue has been excised, or how strong or persistent dilatation has been exercised, the cicatricial tissue steadily advances in the process of healing from the bottom of the cut. If the denuded surface were to heal at once through its entire extent a simple incision would be sufficient to cure the most obstinate case. But this never occurs. Whether the denuded surface be cutaneous or mucous, healing always begins from the apex and progresses toward the edge, by this means gaining support for the new formation from the healthy surface behind it. This is a chief characteristic of cicatricial tissue and the very cause of the adhesions we are considering, so that in our endeavors to cure we are simply subjecting our patients to an alternation of cause and effect. As a means of obtaining a permanent opening, several years ago I devised the operation which I will now describe, and which has accomplished the end sought for. My excuse for making further mention of it is that time and experience have demonstrated its practicability, that it is not a complicated operation, and that it is not as well known as I would like to have it.

To be brief, the similarity of this condition to that known as web finger presented itself, and it occurred to me to adapt to this class of cases the well-known operation of inserting a ring through the web at the base of the web, leaving it there until cicatrization had taken place around it, and then cutting through the web and leaving the edges to heal, reunion being always prevented by the presence of the narrow strip of cicatricial tissue at the base of the cut. The application of this method proved to be successful, and I have now notes of thirteen cases in which it has been tried with complete success, and one in which it proved a complete failure. Of these thirteen cases, only one was non-syphilitic; but I shall give the history of that one also as showing the result of a single operation on a healthy subject. In the other cases resort was had to the operation several times before relief was afforded. The failure was in the person of a negress, subject to an ultra-severe infection of syphilis, in whom every effort at repair was nullified by destructive ulceration, and whose habits and surroundings were such as to preclude any hope of ultimate success. In order to render the operation intelligible a brief recital of the various steps may be made. The instruments necessary, which were made for me by the Ford Surgical Instrument Company, consist of two right-angled curved staphylorrhaphy needles, right and left, two small cervix hooks, a pair of long angular mouse-toothed dressing forceps, and a pair of angular scissors.

In addition to these, two delicate probe-pointed knives, with razor edge and back, the cutting projection bent at right angles three fourths of an inch from the tip, and this portion gradually increasing in width from the tip to the angle. The knife is mounted with a round shank, four inches in length, inserted in a suitable handle of the same length. Carbolized surgeons' silk, Nos. 13 and 14 or 16, is also needed.

The steps are as follows: The parts are thoroughly cocaineized from above and below. There is no case reported in which a slight opening has not been found. Usually it is present posterior or to one side of the uvula. The curved needle, threaded with a long length of the finer silk, is then passed through this opening, care being taken not to wound the membrane. The point is then in the nasopharyngeal chamber above the adhesion. It is then carried as far laterally as the radius of the curve will permit, and brought down through the adhesion as far back as possible and on a plane parallel to the pharyngeal wall. When the point appears through the adhesion the loop of thread is engaged in the hook and pulled out into the mouth and the needle withdrawn. To the end passing through the central opening is then attached a length of the thicker, heavier silk braid (No. 16). Traction is then made on the other end of the thread, and, using the forefinger as a guide, the braid is gradually drawn through the canal made by the needle. The braid should be long enough to allow ease in tying. The two ends are then tied in a square knot (not a "granny" knot, which will soon undo) near the tissue inclosed in the loop, but not close enough to strangle it. When the double knot is firmly tied, the ends are cut off, and by a process of coaxing with the hook, the loop is pulled around until the knot passes up through the central opening into the nasopharynx, where it is not a source of annoyance to the patient.

This loop is left in position for a period of a week to two weeks, according to the rapidity of healing. The movements of the pharynx prevent its becoming attached at any point. At the end of this period the little canal in which the loop lies will have become cicatrized and firm tissue. The loop is then cut and withdrawn, leaving the canal free. The parts are then douches with an alkaline solution and cocaineized. The right-angled knife is then pushed carefully through the cicatricial canal with its edge toward the median line, and the tissue intervening between it and the central opening is cut through, care being taken not to injure the tissue lying at the back of the knife. The parts are then kept clean for a few days, when healing will have taken place along the cut edges; but they will remain separated because of the narrow band of cicatricial tissue at the apex of the cut, and the nasopharynx will be opened by just so much as the depth of the incision. It may be necessary to repeat the operation several times on each side until the required space is obtained. One must look for a small amount of contraction afterward, but the passage always

remains free and functionally adequate. In all the cases which have been operated on the resultant opening has been large enough to admit freely a No. 3 laryngeal mirror. After the first operation, while those in which a second or third operation has been done, secure permanent opening admitting a No. 5 mirror, or approximately the size of a normal passage.

## MOTOR PARALYSIS OF THE LARYNX.

By J. H. McCASSY, M. A., M. D.,  
DAYTON, OHIO.

CASE I. *Thyro-arytenoid Unilateral Paralysis*.—Mr. V., aged twenty-two years, a salesman in a bicycle store, in April, 1896, started on a trip a distance of sixteen miles, with two experienced bicycle riders. When he reached the destination he fell from his wheel and almost collapsed. He was overheated, being drenched with perspiration. In this condition he drank a quart or more of water. A heavy cold followed, and he was confined to bed for over two weeks with laryngitis and gastritis. The latter occasioned frequent vomiting. During all this time his voice was lost, which was attributed to acute laryngitis. He recovered his physical health fairly well in about a month and returned to work, but was of little use as a salesman, with only a whispering voice. Then the writer was consulted. The laryngoscope showed congestion and infiltration of the larynx, particularly the arytenoids. The left vocal cord failed to approximate by an eighth of an inch on attempts at phonation. The unmolested right vocal cord not only came to the median line, but went slightly beyond it on attempts at phonation.

Treatment.—Strychnine, in pill form, commencing with a tenth of a grain daily, which was soon increased to a third of a grain daily. The faradaic current of electricity was applied for ten minutes daily by sponge electrodes. The anode over the larynx and cathode to the nape of the neck and the side of the larynx. A spray consisting of ten grains of zinc sulphate to the ounce of water was used daily on the pharynx and larynx, also a spray of alcohol with a little carboic acid and eucalyptus. Under this treatment the voice had greatly improved in three weeks, and fully recovered in six weeks.

CASE II. *Thyro-arytenoid Unilateral Paralysis*.—Mrs. F., aged thirty years, a private tutor, was referred to the writer by Dr. Pettit, of Dayton, for examination. For many years the patient had been threatened with pulmonary tuberculosis, and she frequently sought a change of climate for the benefit of her health. Dr. Pettit feared the development of tuberculous laryngitis. The voice, save a whisper, was almost totally lost. The laryngoscope showed catarrhal laryngitis, slight enlargement of the arytenoids, and non-approximation of the left vocal cord, on attempts at phonation, by an eighth of an inch. Upon the suggestion of the writer, Dr. Pettit administered a tonic of quinine, iron, and strychnine, with a preponderance of the latter. The following sprays were used daily on the larynx and pharynx: Alkaline, Seiler's, ten grains of sulphate of zinc to the ounce, and alcohol, with a little carboic acid and eucalyptus. The voice was restored fairly well in three weeks, but still better in six weeks.

CASE III. *Chronic Bulbar Paralysis and Insanity*.—Mr. H., aged forty-seven years, a native of West Vir-

ginia, was an inmate of the State insane asylum at Topeka, Kan. He was married and the father of two children. His occupation was that of a bricklayer. The record of the probate court gave heredity as the cause of his insanity. He had suicidal tendencies. Among the first symptoms noticed were impaired articulation; embarrassed speech; imperfect movements of the tongue; failure to whistle or whisper; saliva dripping from his mouth; dysphagia, particularly for fluids; lodgment of his tongue at the bottom of his mouth, and, finally, loss of speech, which occurred a year prior to death. This disease is almost always chronic in its nature, attacking male adults. Prognosis is very unfavorable. The cause of bulbar paralysis in this case was attributed to exposure to cold, undue anxiety for his family, and prolonged physical exertion in his trade as a bricklayer. Death came August 4, 1890, by gradual asphyxia.

The treatment was good diet, good hygienic surroundings, and tonics of quinine, iron, arsenic, strychnine, phosphorus, etc. When deglutition became impossible he was fed with a stomach tube. The autopsy showed atrophy and gray discoloration of the medulla and the gray nuclei in the floor of the fourth ventricle, involving the roots of the facial, trifacial, hypoglossal, glossopharyngeal, spinal accessory, and pneumogastric nerves.

CASE IV. *Bilateral Paralysis of the Lateral Crico-arytænoid Muscles due to Hysteria.*—Mrs. D., aged twenty-two years, a dry-goods clerk, consulted the writer in April, 1891. Four years prior to this she had sustained sudden loss of her voice. Treatment under an eminent general practitioner failed to restore it. About six months after she lost her voice she was agreeably surprised to find sudden and complete restoration of it while entertaining guests one day. About eight months after this, on arising one morning, she was horrified to find herself unable to speak save in a whisper. Three years had elapsed, and although she had been under treatment of several eminent general practitioners, her voice had not returned. She said a Cincinnati throat specialist had advised her that treatment would be useless, and she gave up in despair. She suffered occasionally with slight cough. She continued to fill her position as clerk in the store. The laryngoscope showed subacute laryngitis; the vocal cords were freely movable, but failed by a twelfth of an inch to approximate on attempts at phonation.

The patient was delicately and sensitively organized; was anæmic, and in rather frail health. The writer has no doubt but that this patient will some day, in less than ten years, recover her voice.

CASE V.—Miss M., aged twenty-eight years, had lost her voice two years before. The laryngoscope showed her larynx to be paler than normal and non-approximation of the vocal cords by an eighth of an inch on attempts at phonation. It was ascertained from the friends of this patient that her sexual functions had become perverted. This is of frequent occurrence in cases of hysterical aphonia. In both these cases the patients suffered from slight cough.

The inferior (recurrent) laryngeal nerves innervate all the muscles of the larynx except the crico-thyroids and the two little depressors of the epiglottis. These are supplied by the superior laryngeal nerves. The arytænoid muscle is supplied by both nerves. The superior laryngeal and the inferior (recurrent) laryngeal

nerves are branches of the pneumogastric and receive motor filaments from the spinal accessory nerves. Of course these nerves have sensory fibres, but for practical and clinical purposes they are motor nerves. This motor innervation produces physiological movements in the larynx, as abduction, adduction, and tension of the vocal cords. Motor paralysis of the larynx may be caused by, first, disease or injury of the brain, particularly about the floor of the fourth ventricle and medulla, where the nerves supplying the larynx have their origin, as in Case III. Second, injury of, or pressure upon, these nerves outside of the cranium, as in Cases I and II. (The lesion was peripheral in these cases.) Third, abnormal conditions of the muscles of the larynx, whereby contraction is prevented. Fourth, systemic disease, which debilitates the muscles of the larynx, rendering them unable to respond to nervous influences, as in Cases IV and V.

It would be impossible to have a central lesion as the cause of a unilateral paralysis of the vocal cords, because the nerves supplying both sides of the larynx are branches of nerves having a common central origin. Injury or pressure upon both of the recurrent laryngeal nerves, outside of the cranium, could cause extensive bilateral paralysis of the larynx, but this would be a rare condition. Central lesion is the most common cause of extensive bilateral laryngeal paralysis.

32 WEST FIFTH STREET.

## A CASE OF MYXEDEMA OF THE THROAT.\*

By JOHN W. FARLOW, M.D.,  
BOSTON.

Miss A. B., aged forty-six years, consulted me two years ago and gave the following history: Her family had always been healthy. At the age of twelve she had chorea and rheumatism, and thinks the heart was slightly affected. Eight years ago she suffered from hoarseness, which lasted a short time. Her speech has gradually thickened the last four or five years, but there has been no trouble in swallowing. She has had to keep the mouth open, because there has been much difficulty in breathing through the nose, and is a very bad sleeper and snorer. Much thin mucus flows from the mouth. She says people do not recognize her, as she looks so swollen in the face and her skin is darker. The eyes project somewhat, and she is thin and stiff under the lower jaw.

She has grown weaker the last two years, and has lost about fifteen pounds, weighing now a hundred and eighty-five. There are dyspnoea and quick respiration, 30 to the minute. The appetite, digestion, and bowels are normal. Menstruation has been normal, but is now disappearing. She is nervous, and the hands and feet twitch. There is no itching. She used formerly to sweat, especially about the head, and still does so somewhat.

\* Read before the American Laryngological Association at its eighteenth annual congress.

The hair is not dry and has not come out to any extent. She thinks her memory has failed the past year. There is nothing abnormal in the urine. The dusky, swollen, stiff face, with open mouth and noisy breathing, were very noteworthy. There was nothing abnormal on anterior nasal inspection. The tongue was swollen and thin and tended to protrude. The soft palate, uvula, and posterior pillars of the fauces were very much swollen, tense, thin, and rigid, but were smooth, symmetrical, and the two sides equally affected. The color was a little pale and there was no ulceration. The same condition was on the posterior pharyngeal wall, except in the median line, and extended up behind the soft palate into the postnasal space like two inflated bands. The swelling did not reach much below the tip of the epiglottis. There was nothing abnormal of the larynx and the thyroid gland was not felt. There was a marked systolic murmur heard all over the heart, especially noticeable over the apex. Pulse, 108.

The great swelling of the uvula and soft palate and the bulging forward of the posterior pharynx served to obstruct the passage of the air through the nose and postnasal space, and was a cause of great discomfort. The swollen tongue and rigid palate caused the speech to be slow and indistinct, and the shutting off of the nasal cavities gave a dead character to the tones.

No serum escaped on puncture of the swollen tissues, so that it was evidently not a serous oedema. There were no nodules of infiltrating new growth, and there was no ulceration. A small piece removed from the pharynx showed an unusual amount of mucous tissue, but nothing else abnormal.

The symmetry pointed to a general and not a local cause, and its long continuance (it had changed but little in appearance in two years) excluded nearly every possible cause. The kidneys were not at fault, and, as there was no oedema elsewhere in the body, it was not likely that the condition in the throat was due to the cardiac trouble.

There was no history of specific disease and specific treatment had no effect.

The only thing that could explain the phenomena was myxœdema, although many of the general symptoms were wanting. The discomfort of which the patient complained was entirely due to the swelling in the throat.

J. D. Gimlette, in his work *Myxœdema and the Thyroid Gland*, London, 1895, page 22, says: "Like the skin, the mucous membranes are altered, as is well seen in the mouth, the soft palate, uvula, pharynx, gums, and tongue, swelling and becoming pale and characteristic. A thick, mucous discharge from the mouth at night has been noticed. The oedema of the mouth may interfere with respiration, and also with swallowing, since slight difficulty in deglutition is not at all uncommon in myxœdema."

Under the use of thyroid extract the patient has, perhaps, made a slight gain, although the appearance of the throat is about what it was two years ago.

Inasmuch as the mucous oedema was principally located about the fauces and in a mechanical way gave rise to most of the patient's symptoms, I have thought the case worthy of being reported, and have called it myxœdema of the throat.

## Therapeutical Notes.

**Ichthylol in Affections of the Eyes.**—Germani (*Gazzetta degli ospedali*, June 20, 1896; *British Medical Journal*, August 22, 1896) finds that lanolin mixed with from ten to fifteen per cent. of its weight of ichthylol is very efficacious in ciliary blepharitis, curing it when the ordinary yellow ointment has failed. Collyria containing from one to three per cent. of ichthylol are very useful in phlyctenular conjunctivitis and in simple catarrhal ophthalmia. Ichthylol is well borne, soon eases the pain, and hastens the cure.

**Cerium Oxalate in the Crises of Tabes Dorsalis.**—According to the *Lancet* for August 22d, Professor Bechterew has employed cerium oxalate in the gastric crises of tabes dorsalis, and with decided success. The number of seizures of vomiting was greatly reduced, the act of vomiting became easier, and at the same time pain, thirst, and nausea were diminished to a great extent. The mental conditions also were improved, restlessness subsided, and sleep returned. Urination is said to have been somewhat hindered, but not to the extent of requiring the use of a catheter. The most important improvement, however, was that food could be retained owing to the reduced number of paroxysms of vomiting.

**The Thyroid Treatment.**—Dr. Van de Vorst, says the *Journal des praticiens* for August 29th, reports cases of cirrhosis of the liver (*Bull. de la Soc. méd. d'Anvers*, June, 1896) in which this treatment led to a considerable amelioration. It is to be regretted, says the writer, that the form of cirrhosis which was treated is not indicated and that it is impossible to know in what the amelioration consisted, for in one case there had been ascites and it would be well to know if it had disappeared. On the other hand, in interstitial nephritis the results obtained by Dr. Van de Vorst were disastrous. In certain medullary affections there had also been an aggravation of the symptoms. In a case of psoriasis, however, the thyroid treatment had given entire success.

**The Treatment of Diabetes.**—At a recent meeting of the Congrès de Nancy, a report of which appears in the *Indépendance médicale* for September 2d, M. Mossé stated that he had employed two different methods of treatment, according to the excess or the deficiency of nutrition. In one patient antipyrine diminished the quantity of sugar, of uric acid, and of urea; but this decrease was transitory. Brewer's yeast and the fresh pancreas, in daily doses of four hundred and fifty grains, gave no results. The difficulty, according to M. Mossé, was in the diet, and he thought that the action of the medicament should be carefully watched.

**Iodide of Potassium causing Numbness of the Skin.**—The catarrhal and cutaneous disturbances, says a writer in the September number of the *Glasgow Medical Journal*, which sometimes follow the administration of potassium iodide are comparatively familiar experiences. Mr. Jonathan Hutchinson, according to the *Archives of Surgery* for July, has frequently noted, as another effect of the remedy, a sense of numbness. He states his conviction that the iodide often produces symptoms which simulate sensory paralysis and cause much anxiety to the patient. The numbness disappears when the use of the iodide is discontinued.

NEW YORK, SATURDAY, SEPTEMBER 26, 1896.

THE SERUM TREATMENT OF SYPHILIS.

In the *Fortschritte der Medicin* for September 1st there is an abstract, by Dr. Dreyse, of Leipsic, of an article of Tommasoli's, chiefly polemical, published in the *Giornale italiano delle malattie veneree e della pelle*, called forth by the recent publications of Maragliano, Neumann, Mauriac, and Pellizzari on the subject of the serum treatment of syphilis. After stating that the treatment has accomplished less in syphilis than in other diseases, he accounts for this state of things by the facts that we know so little about the syphilitic virus and that all the lower animals are proof against the disease. He then enters into a controversy with Pellizzari as to the nature of the immunity of animals to syphilis. He believes it is due to materials that circulate in the blood and is therefore hæmatogenous, while Pellizzari is of the opinion that the cause is closely connected with the tissues, since any congenital immunity must be of that sort, whereas acquired immunity must be set down as hæmatogenous. Tommasoli contends that, in the case of man at least, immunity, although acquired, may owe its cause to the tissues.

According to Pellizzari, the *conditio sine qua non* of immunizing experiments is that some material should be inoculated which, although but slightly virulent, is capable of exciting the production of immunizing substances in the tissues. Is, then, he asks, this condition fulfilled in Pellizzari's experiments, since he uses blood from human subjects whose syphilis is of eight, eleven, and thirteen years' duration? A further objection made by Tommasoli against Pellizzari's experiments is that the most various kinds of serum were used on the same patients. He concedes, however, that possibly an amelioration of the course of the disease was the result.

Tommasoli next takes Mauriac to task for inaccuracies in his historical account of the serum treatment of syphilis, and claims priority for himself; if he was not the first to give serum injections in syphilis, he says, he was certainly the first to reduce the treatment to a practicable method. He then combats Maragliano's contention that the immunizing agent in the lower animals is some substance peculiar to themselves, one of which little can be expected when it is transferred to man; also Pellizzari's doctrine that there is no hope of

finding specific antitoxines in the blood of persons affected with tertiary syphilis. It may be, he says, that what we now call syphilis is really twofold—that we must distinguish between the contagious disease and the non-contagious diathesis, between syphilis and “syphilism” [*sifilismo*].

His most recent experiments are divided into three series. In the first method, which he calls *hydropotherapy*, he used the ascitic fluid of a person affected with syphilitic disease of the liver. This he employed upon seven patients in the secondary stage, most of whom had had no previous specific treatment. The smallest number of injections given in any one case was eight, and the largest thirty-seven, in periods ranging from ten to fifty-seven days, and the total amount injected varied from sixty-eight to three hundred and fifty cubic centimetres. The largest single dose was eighteen cubic centimetres. The fluid was obtained with all antiseptic precautions, and used either fresh or after being kept in sterilized vessels with the addition of a few drops of chloroform. The fluid was injected into the buttocks, and no serious mishap occurred in any case. In most of the patients, soon after the injection there followed indisposition, headache, giddiness, etc., but they always subsided speedily; in some there was a slight elevation of temperature; in several the temperature rose and the weight increased during the treatment. No albumin was ever found in the urine. As to the effect on the disease, all that can be said with certainty is that no new symptoms made their appearance during the course of injections.

In the second method, or *galactotherapy*, he used the milk of two women who had secondary syphilis, latent in one of them. After proper cleansing of the nipples, the milk was pressed out and injected immediately into the muscles of the buttock. Out of seven patients treated by this method, one had gummatous syphilis, but all the others were in the secondary stage. The number of injections varied from three to thirteen, and the total amount injected into any one patient ranged from thirty to a hundred cubic centimetres. Two of the patients in the secondary stage were decidedly improved; the others showed no change. This method was based on the observation that in other infectious diseases, such as tetanus and diphtheria, the antitoxines pass into the milk.

In the third method, termed *myelotherapy*, he employed large quantities of the spinal cord of the ox. He had previously seen syphilitics relieved of malaise and osteocopic pains by eating freely of ox marrow without specific treatment. In all, nine patients were treated in this way. Six of them had severe headache and pains

in the bones and joints; two of the six had before been treated with the ascitic fluid; the four others had had no treatment. The three remaining patients showed fresh lesions of the skin and mucous membranes. The fresh spinal cord of the ox was given either in the form of balls having powdered licorice incorporated in them or in that of an emulsion with milk. The smallest amount given in twenty-four hours was three hundred grains; the largest was fifteen hundred grains. Of the three patients with fresh cutaneous manifestations, none showed any improvement, although the treatment was continued for fifteen, twenty-seven, and thirty days respectively. Of the six others, only three were kept under observation for any considerable length of time; at the end of ten days they were all relieved of severe sufferings and felt perfectly well. The third method, then, so far as these observations go, seems the most promising, but the propriety of classing it as a form of serum treatment may be questioned.

### MINOR PARAGRAPHS.

#### THE EFFECT OF OOPHORECTOMY UPON THE VOICE.

DR. TEICHMANN, of Berlin, has furnished to the *Centralblatt für Gynäkologie* for September 5th an abstract of an article by Dr. Castex, which appeared in the *Revue de laryngologie*, on the influence of removal of the ovaries on the voice, a subject on which Moure had written some time before. Castex reports upon six women, under thirty-five years old, who had been subjected to oophorectomy. In one instance the effect of the operation seemed to be damaging; the voice became harsh, especially in the high notes, and unfitted for singing. In another case, that of a mezzosoprano, four low tones were added to the compass of the voice without any change of its strength or timbre. In the remaining cases either there was no change in the voice or whatever alteration there was could not with certainty be attributed to the operation. The author believes that the chance of damage to the voice from oophorectomy is too small to count as a contraindication to the operation.

#### DR. LYDSTON'S OVER THE HOOKAH.

A BOOK of humorous and sentimental sketches entitled *Over the Hookah*, by Dr. G. Frank Lydston, of Chicago, is about ready for publication. We have been favored with advance sheets of nearly the whole of it, all that has thus far been printed, and we have been charmed with the author's way of saying things and with the substance of what he has to say—most of all, however, with the illustrations, which are from his own designs. Much of the matter has more or less to do with medicine, and every doctor ought to read the book. We predict that Dr. Lydston will be called upon for more light writing.

### ITEMS.

**Bellevue Hospital.**—On Monday, October 5, 1896, the New York city civil service boards will hold a competitive

examination at their office (new Criminal Court Building) for the position of house physician at Bellevue Hospital. This position requires a knowledge of the treatment of the insane and pays a salary of \$1,200 per annum. Citizens of the United States, residents of New York State, may procure applications from S. William Briscoe, secretary.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 22, 1896:

DISEASES.	Week ending Sept. 15		Week ending Sept. 22	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	44	14	49	6
Scarlet fever.....	27	2	26	3
Cerebro-spinal meningitis....	3	4	3	2
Measles.....	42	5	32	0
Diphtheria.....	121	33	135	11
Tuberculosis.....	185	111	184	116
Leprosy.....	0	0	1	0

**The Medical Society of the State of New York.**—The business committee, consisting of the following members, has been appointed: Dr. Seneca D. Powell, No. 12 West Fortieth Street, New York (chairman); Dr. Willis G. MacDonald, No. 27 Eagle Street, Albany; Dr. Ernest Wende, No. 271 Delaware Avenue, Buffalo. Communications regarding papers to be presented at the next annual meeting of the society, to be held in Albany, on January 26, 27, and 28, 1897, may be addressed to either of them or to the president, Dr. James D. Spencer, of Watertown.

**The Albany Medical College.**—The Bender Hygienic Laboratory, in connection with the college, on Lake Avenue, adjoining the Dudley Observatory, is completed and will be ready for use by the classes in histology, pathological anatomy, and bacteriology during the ensuing session. Dr. George Blumer, late of the Johns Hopkins University, has been appointed director of the laboratory. Dedictory exercises will be held at the laboratory in October and will be announced.

**The Death of Professor John Eric Erichsen,** the well-known London surgeon, is announced as having taken place on Wednesday, the 23d inst. He was seventy-eight years old.

**Changes of Address.**—Dr. W. H. Bates, to No. 50 East Sixty-fourth Street, New York; Dr. Henry J. Garrigues, to No. 716 Lexington Avenue, New York; Dr. Grace Peckham Murray, to No. 48 West Fifty-second Street, New York.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 13 to September 19, 1896:*

KIMBALL, JAMES P., Major and Surgeon, is relieved from duty at Fort Wingate, New Mexico, and ordered to Fort Columbus, New York, for duty, relieving HOFF, JOHN VAN R., Major and Surgeon. Major Hoff, on being thus relieved, is ordered to Vancouver Barracks, Washington, for duty, relieving EBERT, RUDOLPH G., Captain and Assistant Surgeon. Captain Ebert, on being thus relieved, is ordered to Philadelphia, Pa., for duty as Attending Surgeon and Examiner of Recruits, relieving GRAY, WILLIAM G., Captain and Assistant Surgeon. Captain Gray, on being thus relieved, is ordered to Fort Apache, Arizona, for duty, relieving RAND, IRVING W., First Lieutenant and Assistant Surgeon. Lieutenant Rand, on being thus relieved, is ordered to Fort Clark, Texas, for duty.

DAVIS, WILLIAM B., Captain and Assistant Surgeon, is relieved from duty as Attending Surgeon and Examiner of Recruits in New York city, to take effect upon the completion of his examination for promotion, and ordered to Fort Brady, Michigan, for duty, relieving RICHARD, CHARLES, Captain and Assistant Surgeon. Captain Richard, upon being thus relieved, is ordered

to New York city as Attending Surgeon and Examiner of Recruits.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon, is relieved from duty as Attending Surgeon and Examiner of Recruits, Baltimore, Md., to take effect on completion of his examination for promotion, and ordered to Fort Sherman, Idaho, for duty.

CARTER, W. FITZHUGH, Captain and Assistant Surgeon, will be relieved from duty at Fort Sill, Oklahoma Territory, October 1, 1896, and ordered to Baltimore, Md., as Attending Surgeon and Examiner of Recruits.

PURVIANCE, WILLIAM E., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Sherman, Idaho, and ordered to Fort Columbus, N. Y., for duty, relieving KIRKPATRICK, THOMAS J., JR., First Lieutenant and Assistant Surgeon. Lieutenant Kirkpatrick, on being thus relieved, is ordered to Fort Douglas, Utah, for duty, relieving DE SHON, GEORGE D., First Lieutenant and Assistant Surgeon. Lieutenant De Shon, on being thus relieved, is ordered to Washington Barracks, D. C., for duty.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending September 19, 1896:*

McMURTRIE, DANIEL, Medical Inspector. Promoted to Medical Director from September 3d.

HENEBERGER, L. G., Surgeon. Detached from Naval Hospital, Widow's Island, Maine, ordered home, and then to await orders.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending September 15, 1896:*

CARTER, H. R., Surgeon. Granted leave of absence for twenty-four days from September 15, 1896. September 14, 1896.

STONER, J. B., Passed Assistant Surgeon. Granted leave of absence for thirty days from September 24, 1896.

STIMPSON, W. G., Passed Assistant Surgeon. Granted leave of absence for thirty days from date of being relieved by Passed Assistant Surgeon S. D. BROOKS. September 14, 1896.

EAGER, J. M., Passed Assistant Surgeon. Granted leave of absence for sixty days from December 1, 1896. September 2, 1896.

PROCHAZKA, EMIL, Assistant Surgeon. To proceed from Detroit, Michigan, to Cairo, Illinois, for temporary duty for thirty days from October 1, 1896. September 12, 1896.

CUMMING, H. S., Assistant Surgeon. Granted leave of absence for twenty-six days from October 25, 1896. September 15, 1896.

## Births, Marriages, and Deaths.

### Married.

PAINE—PADDOCK.—In Providence, Rhode Island, on Tuesday, September 15th, Mr. George Law Paine and Miss Elizabeth Mary Butler, daughter of the late Dr. Arthur McLellan Paddock, of St. John, New Brunswick.

THORNE—WHITTAKER.—In Dayton, Ohio, on Thursday, September 17th, Dr. Harry Thorne and Miss Hester Anna Whittaker.

### Died.

BELLAMY.—In Wilmington, North Carolina, on Sunday, August 30th, Dr. John Dillard Bellamy, in the seventy-ninth year of his age.

BENSON.—In Noblesville, Indiana, on Tuesday, September 8th, Dr. J. L. Benson, aged seventy-nine years.

BERNACKI.—In Schandau, Saxony, on Thursday, September 17th, Dr. Charles Bernacki, of New York, aged eighty-four years.

DAWSON.—In Charleston, South Carolina, on Thursday, September 17th, Dr. John L. Dawson.

DAY.—In Farmington, Delaware, on Friday, September 4th, Dr. Asbury M. Day, aged sixty years.

FERRY.—In East Boston, Massachusetts, on Wednesday, September 16th, Alice, daughter of Dr. James F. Ferry.

HILDRETH.—In Southampton, N. Y., on Wednesday, August 12th, Dr. Charles Lotin Hildreth, aged forty years.

LIVEZEY.—In Yardley, Pennsylvania, on Monday, August 31st, Dr. Abraham Livezey, in the seventy-third year of his age.

LOCKWOOD.—In Crystal Springs, Mississippi, on Sunday, September 20th, Dr. B. M. Lockwood, aged twenty-six years.

MATHESON.—In Brooklyn, on Saturday, September 19th, J. Anna, wife of Dr. A. Ross Matheson.

RANDALL.—In Brighton, Massachusetts, on Saturday, September 19th, Dr. Charles L. Randall, aged fifty-five years.

SZABARY.—In New Orleans, on Friday, September 18th, Elizabeth Hart, wife of Dr. Latzi Szabary, aged thirty-eight years.

## Letters to the Editor.

### ALBUMIN TESTING.

BROOKLYN, September 9, 1896.

To the Editor of the New York Medical Journal:

SIR: In an article on Albumin Testing in the last issue of the *Journal*, page 326, by A. R. Elliott, M. D., there appears an error which seems to have been an oversight. On page 327, second column, the statement is made that albumin is the only proteid affected by the potassium-ferrocyanide test. In fact, albumin, globulin, albuminates, and some of the proteoses are precipitated by it. On page 328 the same error also occurs. On this same page it is stated that peptone gives a positive reaction, i. e., is precipitated by ammonium sulphate, while proteose is not. As the reverse of this statement is true, it is to be presumed that this error was accidental.

The separation of the proteids by the method given does not distinguish between albumin, globulin, and the albuminates. They are all classed as serum albumin, although it must be admitted that, for clinical purposes, the distinction is not very important.

A better method for the detection of the proteids to be found in the urine is the following:

1. Test a portion of the urine with Tanret's test. If a positive reaction is obtained, heat the solution to boiling. Albumoses, peptone, and alkaloids dissolve, while serum albumin, egg albumin, serum globulin, mucin, nucleo-albumin, albuminates, and resins remain.

2. Treat the undissolved coagulum with alcohol, when the resin, if present, dissolves.

3. Dilute a portion of the urine with an equal volume of water, and add an excess of acetic acid to precipitate the mucin and nucleo-albumin. Filter off the precipitate, wash with water containing a few drops of acetic acid, perforate the paper, and wash the precipitate into a test tube with a fine jet of water from a wash bottle or pipette. Boil the liquid containing the precipitate with twenty-five per cent. of HCl or H<sub>2</sub>SO<sub>4</sub>, neutralize with liquor potasse or liquor sodæ, and test with Fehling's solution. If mucin is present, the copper is reduced. The separation of mucin and nucleo-albumin is tedious, and, owing to the small quantity of the latter usually present, is unsatisfactory.

4. Boil ten cubic centimetres of filtrate from three,

or the original urine with three or four drops of acetic acid:

(a) Precipitate, *albumin* or *globulin*.

(b) No precipitate, *albuminates*, *albumoses*, or *peptones* may be present.

5. If *albumin* or *globulin* is present, saturate a portion of the urine with  $MgSO_4$ , or add an equal volume of saturated solution of ammonium sulphate. A precipitate, *globulin*, *proteo-* and *hetero-albumoses*. The last two dissolve on heating the solution. If *albumin* or *globulin* is absent (b), neutralize the urine with a dilute alkali, if the urine is acid, or with a dilute acid if it is alkaline, when a precipitate will show *acid-albumin* in the first case, or *alkali-albumin* in the second.

6. If neutralization produces no precipitate, *albumoses* or *peptone* may be present. Try the biuret test with Fehling's solution. Rose-red color, *albumoses* or *peptone*.

7. If *albuminates* are absent, saturate a portion of the filtrate after removing the *albumin* and *globulin*, as under 4, with crystals of ammonium sulphate. A precipitate, *albumose*.

8. To the filtrate from 6 add Tanret's solution. A precipitate, *peptone*. Confirm with Fehling's solution. (See under 6.)

E. H. BARTLEY, M. D.

#### ERRORS IN MEDICAL LITERATURE.

BROCKTON, MASS., September 14, 1896.

To the Editor of the *New York Medical Journal*:

SIR: In the last issue of your *Journal*, I note in Mr. W. J. Robinson's letter a misquotation. He says that Professor Morrow recommends in his *System* the tincture of chloride of zinc, etc. Being a possessor of that *System*, and wishing to correct such a misstatement, I took down volume i and examined the reference—volume i, page 1013—and I find that Professor Morrow recommends the tincture of chloride of iron. He says: "I am accustomed to order the bromide, fifteen grains, in combination with tincture of chloride of iron, fifteen drops, after each meal, with a double dose at bedtime."

I think it due this carefully written set of books that, so long as such an error does not exist, the statement that it does should be corrected.

C. BURTON CONNER, M. D.

[In the first issue of the *System* tincture of chloride of zinc was named, by mistake; but as soon as the error was discovered iron was substituted. Both our correspondents are therefore right, so far as the quotation goes.]

#### PROFESSOR KLEBS'S ANTIPHTHISIN.

ASHEVILLE, NORTH CAROLINA, September 8, 1896.

To the Editor of the *New York Medical Journal*:

SIR: I notice your recent comments upon the position of Professor Klebs as to American patents, in reference to the code of the American Medical Association, which would imply that it was I who kept Professor Klebs in ignorance of the provisions of the code, and that therefore any possible violation on the part of Professor Klebs is in fact chargeable to me.

Permit me to correct this impression by stating that Professor Klebs applied for a patent in the United States for the process of manufacturing antiphthisin in 1893, therefore a year before I ever met him or entered into any relations with him.

When Professor Klebs contracted with the Winyah

Hotel and Sanitarium Company, he represented that he had an American patent on antiphthisin which was ready to be issued to him, and which he expected to find on his return to Germany. He assigned this patent to the Winyah Hotel and Sanitarium Company in order to justify them in carrying out the contract under which Professor Klebs was to be paid a salary for a period of ten years, and which further implied the equipment and maintenance of a laboratory for that period.

Prior to the signing of this contract I explained very fully to Professor Klebs the position of the American Medical Association toward patents, and it was therefore agreed between Professor Klebs and myself that, in order to give no offense, the patent should be owned by the company, and should never be claimed. In other words the company would hold it only in its relations to Professor Klebs.

After Professor Klebs made this contract and agreement, the patent was found to have been rejected by the commissioner of patents, and therefore a trade-mark on the name was secured by the Winyah Hotel and Sanitarium Co., which, however, has never been claimed, and has been held by this company only to protect it in its relations with Professor Klebs.

The relations between Professor Klebs and the Winyah Hotel and Sanitarium Co. were terminated by Professor Klebs's refusal to report in writing the pathological conditions of animals experimented upon with antiphthisin and other remedies *without first knowing* which of such animals were control animals, which were treated with antiphthisin, and which with other remedies. These experiments were requested and directed to be made by me, in order to remove all personal bias, and to show conclusively the true value of the animal experiment, and the demand seemed justified by the paper of Dr. Trudeau and Dr. Baldwin in the *Medical Record* of December 21, 1895, and by the reply of Professor Klebs to the same in the same journal of January 18, 1896, in which he himself stated that the results obtained in such an experiment depended upon the *good will of the experimenter*. It occurred to me that the good will of the experimenter might drift into wrong directions in either case, and I deemed it perfectly proper that Professor Klebs should report upon the results obtained without the previous knowledge that the animal had been treated with his or any other remedy or at all.

Incidental to the question of the chemical status of antiphthisin, Dr. Trudeau and Dr. Baldwin had arrived at certain conclusions, which were contradicted by Professor Klebs in his reply, and he was further directed to substantiate his position by demonstrating the errors of Dr. Trudeau and Dr. Baldwin, which vitally affected his claims published in his book (*Tuberculosis*, Leopold Voss, Leipzig, 1893) as well as his claims of his discovery as set forth by him in his patent application.

This Professor Klebs also refused to do, and that, together with the animal experiments, will receive more notice and light after we have finished the investigations now in progress and nearing completion in our laboratory, which Professor Klebs declined to make.

I am perfectly willing to assume the responsibility as to any violation of the code of ethics of the American Medical Association, but I do not propose that Professor Klebs shall shield himself by pleading ignorance on a subject which was discussed time and again between us, both before and after he made his contract, the result of which was, as stated before, that both of us agreed to avoid giving offense by making no claims for

either patent or trade-mark, and none have ever been made either upon the labels or other printed matter in connection with antiphthisis.

KARL VON RUCK, M. D.

## Proceedings of Societies.

### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eighteenth Annual Congress, held in Pittsburgh, Pa., Thursday, Friday, and Saturday, May 14, 15, and 16, 1896.*

The President, Dr. WILLIAM H. DALY, of Pittsburgh, in the Chair.

(Continued from page 363.)

**Tuberculous Infection of the Lymphoid Tissue of the Pharynx.**—Dr. JONATHAN WRIGHT read a paper on this subject. (See page 412.)

Dr. H. L. SWAIN said: I consider this one of the most valuable contributions we have had on this subject. We are all aware that the glands of the neck are frequently enlarged in cases of adenoids and of enlarged tonsils, and it is a relief to my mind to know that such swelling is probably hardly ever tuberculous. It has been demonstrated by excision of these enlarged glands in the adult that they may be tuberculous, and I have always had a suspicion that this condition was left over from the lymphadenitis of childhood. Another good point was brought out by these pictures—the bacilli wandering through the epithelium of the larynx, which is always more dense and seemingly more resisting than in the tonsils. Those who have made many sections of these latter organs must have been impressed with the condition of the epithelium in every case of enlarged tonsil, as it is perforated by many thousands of holes through which the leucocytes pass, so that it resembles a honeycomb. When we think of the possibility of infection, it is a wonder that the tonsils are not literally a hotbed of the tuberculous infection. This bears very nicely upon the point that the tonsils must have some protective action in the matter, or are very non-absorptive.

Dr. WRIGHT said: The large glands in the neck, I think, are very frequently tuberculous, and the fact that tubercle bacilli can not be found does not prove that they have not been there. It has been shown that the tonsils are very poor structures for absorption, and very little evidence of absorption through the tonsils has been obtained. Whether bacilli have passed through but have not lodged it is impossible to say, but it is a fact that they are frequently found in the lymphatic glands below. It has been said that in adults with phthisis the tuberculous infection has been a retrogressive one, from the root of the lung upward, whereas in children the evidence shows that the infection has been downward.

**The Relation of Acute Diseases of the Nose and Throat to Disorders of Digestion.**—Dr. M. R. BROWN, of Chicago, read a paper on this subject. (See page 294.)

**The Relation of Chronic Diseases of the Nose and Throat to Disorders of Digestion.**—Dr. T. R. FRENCH, of Brooklyn, read a paper on this subject. (See page 356.)

Dr. JOHN O. ROE said: There is no question but that the upper air-passages are markedly affected by dis-

turbances or diseased conditions of the stomach. This is well illustrated by the frequent occurrence of influenza or a cold in the head, after excessive eating or drinking, which very often occurs after wine dinners and the like, as a result of the gastric irritation which is reflected from the stomach to the nasal passages, through the sympathetic nerves, producing in the nasal cavity excessive turgescence of the vessels from the lack of inhibitory control. Headaches that so frequently follow the excessive indulgence of the appetite are produced in the same manner. And in the treatment of these disturbances nothing is of more assistance in quickly relieving a cold in the head or a headache arising from this cause than a brisk saline laxative, one of the most serviceable of which I have found to be liquor magnesii citratis. Affections of the stomach are also caused in many cases by disease in the upper air-passages. The principal manner in which diseases of the upper air-passages affect the stomach is by the passage of secretions from the nose and throat into the stomach, carrying with them the bacteria which produce fermentation or decomposition in the stomach, and in some cases very well marked disturbances.

Dr. WRIGHT said: I have been struck by some Italian observations in regard to the bacterial condition of the nasal mucus during acute coryzas. *Sarcinae ventriculi* were found in normal cases in moderate numbers, but in acute coryza they are much increased. In children, acute coryza frequently ends in a disturbance of the stomach. Possibly there may be some etiological connection between the two. In adults one is not so apt to find stomach disturbance, as they do not swallow their mucus as a rule. In chronic coryza and post-nasal catarrh I have never noticed any special tendency to dyspepsia. Both affections are too common in America to reason from one to the other in regard to cause and effect.

Dr. W. E. CASSELBERRY said: Dr. Turck, of Chicago, has made an effort in a scientific way to determine the dependence of stomach diseases upon nasopharyngeal affections. The instrument he has devised he calls a gyromele, with which he swabs out the stomach. He subjects the secretions thus extracted to bacteriological examination, and asserts that in several cases of pharyngeal disease with muco-purulent secretions he has discovered the same micro-organisms in the stomach that were present in the nose and nasopharynx. He asserts also that in these cases, without other treatment, the correction of the nasopharyngeal trouble by a laryngologist, to whom the cases were referred, has cured the stomach disease. I do not know how accurate this is, but it seems to be a step along the proper line. It is of more value than examinations from a clinical standpoint only, as, unsupported by experimental work, clinical observation must always leave a doubt in this matter. The next step would be for others to be able to confirm Dr. Turck's interesting experiments.

Dr. G. V. WOOLEN, of Indianapolis, in continuing the discussion of papers by Dr. Brown and Dr. French, said: Since Dr. Wright published his paper a few years ago, showing what a number of bacterial agents could be found in the nasopharyngeal mucus, I have accepted it as a fact that the gastro-intestinal trouble was due to this. The trouble in the stomach may cause or be the cause of the nasopharyngeal trouble, and investigations have proved this. I have been accustomed to say to my patients, in order to discourage the swallowing of this mucus, that I believed the nastiest part of the whole

human organism was the nasopharynx, and I believe this to be true. I must object to Dr. Wright's remark that adults do not swallow their secretions, and I think you will hear me out in this. You will oftentimes see a collection on the posterior wall of the pharynx, and before you can tell your patient to clear his throat the collection will have passed into the stomach.

Dr. ROE said: While in Atlanta, attending the meeting of the American Medical Association, last week, I had an interesting conversation on the subject with Dr. Turck, of Chicago, who has given the subject of bacteria of the stomach a very large amount of attention. He said that he found in many cases the same bacteria attached to the walls of the stomach that he found in the nasopharynx, which had originated in the nasopharynx and found their way into the stomach. Recognizing the fact that the bacteria in the stomach had originated in the pharynx, he invariably referred such cases to the laryngologist for the treatment of the nasopharynx.

The finding of the same bacteria in the stomach that are found in the nose would not be a proof that gastric disease is caused by the nasal trouble. So far as I know, nothing has been advanced to show that pyogenic bacteria, the characteristic pathogenic micro-organisms of the nose, have any irritative effect on the intact mucous membrane of the stomach. It seems probable, however, that the raw albumin of the post-nasal secretions swallowed may cause dyspepsia.

Dr. F. E. HOPKINS, of Springfield, Mass., said: There is one point to be borne in mind, and that is, that although the nasopharynx and the nasal passages may contain bacteria, we must remember that we can cut into the tissues without producing any serious results from the local irritation of the bacteria, and if they do not produce serious results in the open wound it is worthy of further thought whether much irritation would be produced upon the mucous membrane of the stomach.

Dr. BROWN said: I did not attempt to state that the relationship existing between acute inflammation of the nasopharynx and of the stomach was a matter of theory, but that clinical evidence seemed to demonstrate that there was a relation between the two. Regarding Dr. Turck's observation—i. e., that he found the same organisms in the upper air tract and in the stomach—he has reported some nine cases in which careful bacteriological examinations were made of the secretion taken from the nose and throat, and then using a gyromele in the stomach he finds the same organisms present. After restoring the mucous membrane of the nose and throat to a healthy condition the bacteria disappear from the stomach. He mentions one case in particular of an acute inflammation in which the same organisms were found in the nasopharynx and in the stomach. The condition of the stomach improved after relieving the inflammation of the upper air-passages.

Dr. FRENCH said: When Dr. Robinson, in the paper which he read before this association several years ago, expressed his belief that discharges from the nasopharynx were capable of exciting gastric catarrh, exception was taken to the statement by some of the members speaking to the paper.

I have been much gratified, therefore, in the discussion today to hear this belief endorsed. Boas, of Berlin, the specialist in gastro-intestinal disorders, is a strong believer in this theory, as is also Fischer, of New York, who devotes himself to the same specialty.

I had expected, in the discussion of the relation

of digestive disorders to acute diseases of the nose and throat, that Dr. Duncan Burkley's theory of the cause of common colds would be mentioned. He believes that colds are due to a hyperacidity of the gastric secretions, and that the administration of an alkali, preferably the bicarbonate of sodium, will often abort them if given in time, or materially improve the nasal and throat conditions if given at any time during the course of the attack. I have tried this method of treatment in many cases and with such gratifying results that I can not but believe that there is much truth in the theory. Chemical analyses, which I believe are now being made, will, no doubt, soon settle this question. If the theory is a correct one it constitutes a very strong argument in favor of the intimacy of the relationship between the diseases of the digestive and those of the upper air tracts.

**A Case of Myxedema of the Throat.**—Dr. JOHN W. FARLOW, of Boston, read a paper on this subject. (See page 421.)

**The Treatment of Diseases of the Nose and Ear with Oxygen.**—Dr. GEORGE STOKER, of London, contributed a paper on this subject. (See page 222.)

**Erysipelas of the Air-passages.**—Dr. WILLIAM PORTER, of St. Louis, read a paper on this subject. (See page 221.)

**Seropurulent Maxillary Sinusitis in Chronic Lead Poisoning.**—Dr. H. L. WAGNER, of San Francisco, read a paper with this title. (See page 222.)

(To be continued.)

## AMERICAN NEUROLOGICAL ASSOCIATION.

*Twenty-second Annual Meeting, held in Philadelphia, on Wednesday, Thursday, and Friday, June 3, 4, and 5, 1896.*

The President, Dr. F. X. DERCUM, of Philadelphia, in the Chair.

(Continued from page 395.)

**Progressive Muscular Atrophy of Sudden Onset.**—Dr. THEODORE DILLER, of Pittsburgh, related the details of a case which had come under his observation three years before, and stated that the sudden onset of palsy followed by atrophy and the absence of sensory phenomena had led him to diagnose the case as one of poliomyelitis acutiorum. The beginning of the patient's trouble had been in an ophthalmoplegia. After an absence of two years the man had again come under his care, when the atrophy and loss of power in the muscles had decidedly increased. The biceps and triceps and the scapular and ulnar groups had become involved and the finer movements of the fingers had been lost, also the power of supination. At that time the patient had been unable to adjust or remove his clothing unaided. There had been a marked decrease in the response both to galvanism and faradism in the paralyzed muscles. Dr. Diller considered the case could be fairly regarded as one of progressive muscular atrophy, as the progressive feature had been for two years the most important point in the case. Ophthalmoplegia is a symptom of progressive muscular atrophy must be rare, for but scant references were made to it in literature. Strychnine had a very marked effect in staying the progress of the disease.

**Pitting about the Hair-cups, a Trophic Change in the Skin in Certain Nervous Disorders of Central Origin.**—Dr. WILLIAM BROWNING, of Brooklyn, described a presumably hitherto unrecognized alteration in the skin. From some seven or eight years' observation of such

cases he was able to give the limits of its occurrence. So far, it had been seen only in progressive muscular atrophy of spinal origin or in cases complicated with atrophy evidently likewise due to chronic precornal disease. In other troubles attended by atrophy, such as infantile palsy, neuritis, pseudo-hypertrophy, etc., it had not been found. He hoped that it might prove a useful help in diagnosis, especially between the forms due to peripheral and those due to central disease. The change consisted of an areolalike faint depression, frequently oval, in the direction of the lines in the skin, though it might be irregular or circular in form, about the exit of each hair. Usually the depression was a trifle paler than the surrounding skin, resembling, but not really being, a minute scar. It was not observed in specially hairy regions like the scalp, but only over the seat of muscular atrophy, notably on the leg and thigh, also on the upper extremities. All these patients had reached or passed middle life.

**Myelosyringosis limited to One Posterior Horn in the Cervical Region, with Arthropathy of the Shoulder and Ascending Degeneration in the Pyramidal Tracts.**—

This was the subject of a paper by the PRESIDENT and Dr. WILLIAM G. SPILLER, of Philadelphia, who stated that, three years after a strain of the back, the patient had begun to suffer from pains in the legs, a band-like pain about the lower part of the chest, weakness in the lower limbs, and a spastic gait. Complete paraplegia with contractures, more marked on the right side, wasting of the lower limbs, and paralysis of the bladder and rectum had developed later. Cutaneous sensibility had been lost in the legs and upon the trunk as high as the nipple on the right side and a little above the umbilicus on the left. The sense of temperature had been absolutely lost over the right arm, the right shoulder, and the right side of the neck, and also upon the adjacent part of the right side of the trunk above the nipple line. There had been some analgesia of the right arm. The right shoulder joint had begun to swell, and, owing to a rupture of the capsular ligament, cellulitis, with redness and local heat, had been produced, but with little or no pain. In extension, the humerus assumed the position of a subglenoid luxation. Death had been due to exhaustion.

At the autopsy the capsule of the right shoulder joint had been found to be much thickened and roughened on the inner surface. The head of the humerus had disappeared, the bone having been eroded to some little distance below the surgical neck. A cystic tumor containing a friable fatty material was found in the axilla. The surface of the glenoid cavity was much eroded, roughened, and porous, it was abnormally large, and an extensive bony deposit had taken place along its edges. The coracoid process exhibited a thick and firm accretion around its entire edge.

Sections had been made from the level of nearly every spinal root and from many spinal ganglia. By the microscopic examination degeneration of the crossed pyramidal tract had been found as high as the substantia reticularis of the second cervical segment and of the direct pyramidal tract as high as the motor decussation upon the right side and for a short distance of the crossed pyramidal tract upon the left. This was believed to have been ascending on account of the following facts: 1. The absence of any microscopical lesion above the medulla oblongata. 2. Degeneration of the crossed and direct pyramidal tracts on the same side of the cervical cord, intense in the lower cervical region near the

lesion, diminishing gradually in intensity in the cervical segments, and finally becoming very indistinct in the upper cervical region. 3. The absence of all degeneration in the anterior pyramids. 4. The long duration of a chronic process.

While certain associative fibres might be considered degenerative in these columns, the entire antero-lateral column contained such fibres, and the degeneration had notably been in the area occupied by the crossed and the direct pyramidal tract. This ascending sclerosis had probably been in greater part due to destruction of motor fibres deprived of their function. Degeneration of the direct cerebellar tracts and of the tracts of Gowers had been traced as far as the inferior peduncles of the cerebellum. Intense pachymeningitis had been noticed from the second lumbar segment to the exit of the third dorsal roots. The arthropathy of the right shoulder had not been due to any special changes in the cord or spinal ganglia. The posterior roots had not been affected where the pachymeningitis had been most intense; the anterior at one part of the dorsal cord had been degenerated. In the entire cervical region, as high as the second cervical segment, the cavity had been limited to the right posterior horn. The gliosis had extended from the extreme end of the conus terminalis to the second cervical segment. The microscopical examination had explained satisfactorily the symptoms observed in life.

Dr. HENRY S. UFSON, of Cleveland, stated that the degeneration in the lateral columns was explicable in two ways: The short fibres might have been affected successively by the lesion, or the degeneration might be in consequence of the myelosyringosis or coincident with it.

Dr. JAMES H. LLOYD, of Philadelphia, said that the foregoing remarks proved that a localizing diagnosis could be made at the present time. This was the sixth case that had been correctly diagnosed at the Blockley Hospital. He thought the diagnosis was a very easy matter.

Dr. B. SACHS, of New York, indorsed what the previous speaker had said as to the diagnosis. As to the sensory symptoms, the line must not be drawn too close. There was frequent variability in the sensory symptoms during the course of the disease.

Dr. KNAPP mentioned a case that had been under his observation, in which the diminution of tactile sensibility had been marked, although in the earlier period of the disease it had been very slight.

Dr. M. A. STARR, of New York, stated that the first case which had been correctly diagnosed in New York had been presented at his clinic. He did not think this disease was a rare one. He had seen three cases lately in which the dissociation of sensation had been well marked and accompanied by trophic symptoms. He also referred to its coincident association with acromegaly. Sometimes there was considerable difficulty in making the diagnosis. He mentioned a case in which it had been difficult to determine whether it was hysteria or myelosyringosis. There had been preservation of tactile sense and hemianæsthesia limited to pain and temperature senses.

Dr. PUTNAM referred to a patient he had observed for many years, in whom there had been constant and severe pains in the back which had led to the suspicion of a tumor. He had been operated upon and his condition improved. Dr. Putnam thought the diagnosis was extremely difficult in children.

Dr. PATRICK was pleased to hear attention called to the coexistence of pachymeningitis. He had seen a case in which both lesions had coexisted.

**Rapidly Fatal Encephalitis resembling Cerebro-spinal Meningitis.**—This was the subject of a paper by Dr. JAMES HENDRUE LLOYD and Dr. JOSEPH SAILER, of Philadelphia. The writers called attention to the fact that fulminating cases of the infectious diseases, such as small-pox, scarlatina, measles, typhoid fever, and spotted fever, occurred in which the diagnosis was exceedingly obscure and the disease was usually quickly fatal. In these cases, as a rule, the most marked symptoms were in the nervous system. There was delirium passing into coma, with depressed cardiac and respiratory centres, with high fever, and, in the cases of the exanthemata, often a purpuric or hæmorrhagic eruption not always characteristic. These cases demanded especially two things: first, the determination of the exact effects upon the nervous system, and, second, the determination of the microbe or toxic agent at work in any given case. The writers could only attempt the former study, as the paper was not intended to deal with the bacteriology of the subject.

The patient was a man, aged twenty-four years, who had been taken suddenly with a chill followed by fever and intense cephalalgia and rhachialgia. He had passed rapidly into a condition of delirium merging into coma. Third-nerve paralysis had supervened, and on the third day a copious purpuric eruption had appeared. This eruption had presented ecchymoses, and, on the hands, lesions like those of erythema nodosum. Blood and pus had been found in the urine, and vomiting of blood had occurred before death. The patient had died on the sixth day. The autopsy had revealed disseminated local lesions in the cerebrum, mid-brain, pons, and post-oblongata. There had been some migrated leucocytes in the circumvascular spaces, little involvement of the membrane, and a diffused nephritis. From extensive microscopical research, the writers were able to report a disseminated local inflammation of the cerebrum. The infection had invaded the brain by way of the connective-tissue structures, blood-vessels, etc., and the nerve tissues proper had been invaded secondarily. From a clinical standpoint the case probably came under the head of spotted fever.

Dr. OSLER said he should like to have heard more in regard to the condition of the kidneys in the case reported. The diagnosis of encephalitis could be readily made. Unless the basal meninges were involved we could not make a positive diagnosis of meningitis, as all the symptoms, such as retraction of the head and clonic contractions of the muscles, might be present in pneumonia and yet nothing was found at the autopsy.

Dr. PUTNAM agreed with the previous speaker that so-called meningeal symptoms might occur without meningitis.

**A Case of Neuropathic Dermatitis.**—Dr. L. A. DUHRING, of Philadelphia, presented this patient, who had been under his observation for six years.

**The Effects of the Fluid Extract of Anhelonium Lævini (the Mescal Button).**—This was the title of a paper by Dr. S. WIER MITCHELL, and read by Dr. WILKINSON SINKLER, of Philadelphia, in which a graphic description was given of the personal experience of Dr. Mitchell as to the exhilarating effects and the production of various visual hallucinations, etc., after the ingestion of a certain quantity of the drug.

**Uncertainties of Cerebral Localization.**—A paper with

this title was read by Dr. WHARTON SINKLER, of Philadelphia.

**Cerebral Abscess situated at the Posterior Part of the External Capsule (involving the Medullary Substance of the First Temporal Convolution; also the Posterior Part of the Lenticular Nucleus, and extending into the Subthalamic Region), with some Considerations in Regard to the Constitution of the External Bundle of Fibres in the Cerebral Peduncle.**—Dr. CHARLES K. MILLS and Dr. WILLIAM G. SPILLER, of Philadelphia, presented the following case: The patient had never had ear-ache, but had suffered during the summer of 1895 from severe headache. On December 20, 1895, he had become unconscious and had had three general convulsions which resembled those of epilepsy. It had been noticed that he was partially paralyzed on the right side and that he could not talk properly. His condition later had improved very much. On January 29, 1896, he had had another attack of partial unconsciousness without convulsions, but with aphasia and decided paralysis. On his admission to the hospital he had been in a condition of stupor; he had not spoken when addressed, and had had almost total right-sided paralysis, incontinence of urine and feces, and entire loss of pain and touch sense over the paralyzed side. It had been found that he had right homonymous hemianopsia, and double papillitis, most marked in the left eye. Death had occurred on February 26, 1896. There had been no evidence at any time of middle-ear disease.

At the autopsy an abscess had been found in the left hemisphere, just above the level of the callosum. Both tympanic membranes had been normal. Microscopical examination of the pus from the cerebral abscess had revealed only the ordinary *Staphylococcus pyogenes aureus*.

The occurrence of epileptoid convulsions at the time of the first attack of unconsciousness, which had probably been due to irritation of the motor fibres within the internal capsule, was worthy of note as an instance of the difficulty in diagnosing cortical lesions. It was not known in what portion of the body these convulsions began. The diagnosis had been made of some morbid process located at the posterior part of the internal capsule, involving the optic radiations and causing pressure.

The abscess had occupied the posterior part of the external capsule and a portion of the lenticular nucleus, and had extended downward into the subthalamic region, but to all appearances it had not cut the fibres of the optic radiations or those of the internal capsule. The loss of function in these tracts had probably been due to pressure. The white matter of the first temporal gyrus had been almost entirely destroyed, and fibres from the upper anterior part of the second temporal had also been cut. As the cavity had been very near the periphery of the first temporal convolution, it would not have been difficult for the surgeon to empty it. Hearing had probably not been seriously affected, although word deafness had appeared to be present. In view of the frequency of cerebral abscess after suppurative processes in the lungs, it might be added that merely spots of catarrhal pneumonia had been found in both lungs at the autopsy. No degeneration had been noticed anywhere in the motor tract. At all parts a good half-inch of sound tissue had existed at the posterior part of the internal capsule in the area corresponding to the optic radiations and Trunk's tract. It had been maintained by Déjerine that fibres arose in the temporal lobe (especially in the second and third convolutions), passed inward below the

putamen, joined the posterior part of the internal capsule in the subthalamic region, and then formed approximately the external fifth of the cerebral peduncle. No fibres from the occipital lobe were found in this lateral bundle of the crus. Déjerine had found this tract of Türk degenerated in six cases of lesions involving the middle and inferior parts of the temporal lobe.

In this case the fibres from the first temporal gyrus had been almost entirely destroyed, as well as those from the upper anterior part of the second temporal convolution, and, as no degeneration had been found within the lateral bundle of the peduncle by Marchi's method, sixty-eight days after the first attack and twenty-eight days after the second, certainly a period sufficiently long for this method, the authors considered that the case demonstrated the fact that no fibres from the first temporal and the upper anterior part of the second temporal gyrus, including a portion of the upper middle of this gyrus, entered Türk's fasciculus. This of course did not render impossible or improbable the origin of such fibres in the lower anterior and in the whole of the posterior part of the second temporal and in the whole of the third temporal gyrus. The fibres which entered the first temporal gyrus were probably connected with the sense of hearing and, being sensory, probably did not degenerate downward, which accounted for the absence of secondary degeneration in the peduncle.

**The Surgical Treatment of Focal Epilepsy; a Critical Analysis of the Result in Nineteen Cases.**—Dr. B. SACHS and Dr. A. G. GERSTER, of New York, stated that for the last six years they had attempted to study in a thoroughly unbiased fashion the results of the various surgical procedures for the cure or relief of partial epilepsies. They had included not only cases due to traumatic injury, but those associated with infantile cerebral palsies or some other acute cerebral condition. Their list of cases did not, however, include those in which the epilepsy was due to tumor. Before detailing their own cases the authors laid special stress upon the unsatisfactory results to be gained by a mere statistical inquiry of the cases reported in literature. The majority of these were reported either too early, or, if reported, they were not properly analyzed. It was their opinion that the results after operative procedures for the cure of epilepsy should not be considered unless at least a period of a year had elapsed since the time of the operation. But they also stated that it was not well to exclude all cases in which the attacks returned soon after the operation, for, in some of these, decided improvement set in later on. A number of authors had condemned every surgical procedure, without in the least attempting to account for the failure to cure or to improve the patient. Thus the mere fact of an addiction to alcohol was of itself sufficient to explain the failure to cure epilepsy by operative procedure. The epilepsy which was developed after a traumatic injury or in association with infantile cerebral palsies was evidently due to secondary degeneration of the association fibres in the hemispheres, and this degeneration originated from the focus of diseased tissue and was generally developed in the course of a year or two. In this same period of time the epilepsy often appeared after the initial injury. Horsley's proposition to excise the diseased tissue and thus prevent the epilepsy was considered to be based upon sound physiological principles, but in practice the results had not been so satisfactory as had been expected, and the authors attributed this

chiefly to the fact that after epilepsy had lasted for a number of years, and after secondary degeneration had been fully established, the excision of the original focus of disease could not be expected to do good. It was important therefore, if possible, to prevent the formation of secondary degeneration in the hemispheres by excision of the diseased tissues, or to prevent epilepsy by early surgical procedures in the case of depression of the skull and other cranial injuries. These nineteen cases had been minutely tabulated with reference to the origin of the trouble and the interval elapsing between the traumatic injury or beginning of the epilepsy, and the operation. The analysis showed that three patients had been positively cured, two greatly improved, and three somewhat improved, while in eleven cases there had been absolutely no improvement. A study of all the cases showed that in those in which there had been improvement the operation had been done within a period of two years after the traumatic injury or the beginning of the disease. The same was true of those cases in which great improvement occurred but not recovery, the failure to cure in these cases having been ascribed to other causes, such as alcoholism or want of proper care after operation. The authors' views and experiences were summed up in the following conclusions:

1. That surgical interference was advisable in those cases of partial epilepsy in which not more than one or at the utmost two years had elapsed since the traumatic injury or beginning of the disease which had given rise to the convulsive seizures.
2. In case of depression or other injury of the skull, surgical interference was warranted even though a number of years had elapsed. But the prospect of recovery was brighter the shorter the period of time since the injury.
3. Simple trephining might prove sufficient for a number of cases, and particularly in those cases in which there had been an injury to the skull or in which a cystic condition was the main cause of the epilepsy.
4. Excision of cortical tissue was advisable if epilepsy had lasted but a short time and if the symptoms pointed to a strictly circumscribed focus of disease.
5. Since such cortical lesions were often of a microscopic character, excision should be practised even if the tissue appeared to be perfectly normal at the time of operation, but the greatest care should be exercised in order to make sure that the proper area was removed.
6. Surgical interference for the cure of epilepsy associated with infantile cerebral palsies might be attempted, particularly if too long an interval had not elapsed since the beginning of the palsy.
7. In cases of epilepsy of long standing, in which there was in all probability a widespread degeneration of the associated fibres, every surgical procedure was absolutely useless.

**A Contribution to the Pathology of Epilepsy and a Resume of the Utility of Operation in Epilepsy.**—Dr. JOSEPH COLLINS and Dr. A. WIENER, of New York, reported two cases in which a portion of the cortex had been excised. The first case was that of a young man, twenty years of age, with the usual symptoms of focal epilepsy, who had had but three attacks. The cortical area for the right hand had been cut out. Microscopical examination of the tissue had shown chronic meningo-encephalitis, obliterative changes in the blood-vessels, changes in the ganglion cells of a degenerative character, and the formation of neuroglia tissue in the softened area. The patient had been operated upon a year before and had since been free from epileptic attacks.

The second case was that of a married woman, thirty years of age, who for six years had had epilepsy of a focal character at first, which later had become general. A similar operation had been performed, and the cortex had shown unmistakable pathological changes.

Dr. W. W. KEENE, of Philadelphia, and Dr. E. M. THOMAS, of Baltimore, reported a case in which a large tumor had been removed from the brain, with wide opening of the lateral ventricle. The patient, a young man of nineteen years, had an excellent family and personal history, and no history of accidents. In December, 1895, he had had an attack of intense headache and vomiting, but without optic neuritis. The latter symptom had followed in the middle of January, with, later on, blindness in the right eye, slight vision remaining in the left; there had been slight protrusion of the left eyeball; the pupils had been equal and normal; the sense of smell, of hearing, and of taste had been unaffected. Paresis of the lower right face had existed; sensation and the muscles of mastication had been unaffected; there had been no muscular weakness in either the arms or the legs, but there had been a good deal of muscular restlessness of the right hand, which had persisted even during sleep. The reflexes had been present; the mental condition had been poor; the patient had been dull and apathetic, and sometimes slightly wandering. After the early headache and vomiting had appeared, these symptoms had not been a marked feature. There had been slight aphasia. Dr. Osler and Dr. Starr had seen the patient with Dr. Thomas, and the conclusion had been reached that there was a tumor in the left frontal lobe, most probably at the base of the second frontal convolution, and probably subcortical. On May 10th, Dr. Keene had operated. The tumor had presented through a rupture of the cortex at the base of the second frontal convolution, as had been diagnosed. The tumor had been easily scooped out by the fingers. The lateral ventricle had then been seen to be wide open. After the operation there had been no increase of the paralysis. In two weeks the patient had entirely recovered. The tumor had been 7.5 centimetres long, 5.5 centimetres broad, and four centimetres deep, and weighed two ounces and a half. It was a hard non-infiltrating sarcoma.

Dr. A. G. GERSTER, of New York, confined his remarks principally to craniotomy in reference to cases of epilepsy. He spoke of the dangers in the use of the trephine and chisel, and recommended the bone-flap operation, as introduced by Krause, which was performed with the aid of the chisel and rongeur. He considered all these methods unsatisfactory and too slow. Incidentally, he exhibited Krause's electrical saw.

The greatest danger in cranial operations, he thought, was due to hemorrhage on account of the prolonged duration of the operation. Therefore any apparatus was desirable that would enable the surgeon to work with rapidity and safety. He presented an American apparatus based on the principles of the dental drill, and said he had used the instrument with satisfaction in four cases.

Dr. M. A. STARR had seen twenty-four patients operated upon, but none had been cured. He had never recommended and would not recommend an operation in idiopathic epilepsy. He had always had the advantage of a skillful operator. These operations should only be done by surgeons who had special experience in this line of surgery, and not by the general surgeon. The excision of cysts was very unsatisfactory, as death

on the table had often followed. He had seen patients operated on very early in infantile epilepsy which had been due to meningeal hemorrhage, without favorable result. When brain tissue, either scar tissue or normal tissue, had been excised, the attacks had also recurred. In eleven cases of brain abscess in which an operation had been done, three patients had recovered. All these cases had been seen at the various hospitals, and they had usually been subsequent to ear disease. Dr. Starr could not agree with Macewen in his view as to the simplicity of diagnosis of cerebral abscess. He thought the days of trephining were over. The last operation that he had witnessed had been done in fourteen minutes and a half with chisels and gouges.

Dr. W. W. KEENE spoke at length on the report of the case presented conjointly by himself and Dr. Thomas, and said that he considered the prognosis favorable. The removal of large tumors seemed to be less dangerous to life than the removal of small ones, as in the search for the latter we were likely to damage the brain extensively. It was only within the last ten years that cranial surgery had really begun. His experience had been moderately large. He agreed with Dr. Starr, as he himself had not seen a single case of epilepsy in which an operation had resulted in a cure. He should be unwilling to accept even two years, but thought three years preferable as the limit for the disappearance of attacks after operation. He had, however, seen considerable amelioration, and therefore thought it worth while to operate in certain cases. He would not operate in cases of general idiopathic epilepsy. The sooner the operation was done after the injury or the beginning of epilepsy the more favorable the prognosis. After epilepsy had existed for five or six years, he would hesitate in operating. He concluded that it would take twenty years of experience in cerebral surgery before this matter could be satisfactorily settled.

Dr. J. H. LLOYD presented a patient with right hemiplegia and contracture, unilateral sweating and flushing of the face, and dilatation of the pupil. The latter symptoms, he said, were due to an irritative lesion of the thalamus.

(To be concluded.)

## Book Notices.

*Burdett's Hospitals and Charities, 1896*; being the Year-book of Philanthropy. Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities. An Exhaustive Record of Hospital Work for the Year, etc. By HENRY C. BURDETT, Author of *Hospitals and Asylums of the World*, etc. London: The Scientific Press (Limited). [Price, five shillings.]

We have heretofore described the features of this annual and have spoken in admiration of its many desirable qualities. The volume for the present year maintains the high standard set by its predecessors and is as remarkable and as valuable as they. The field of statistical information contained within this work is enormous, and when one considers the editorial consideration of timely topics which occupies several of the opening chapters it is apparent that the book well deserves its

subtitle of the *Yearbook of Philanthropy*. The physician must certainly derive much valuable information from this work, and to all who are philanthropically inclined the work must be educational in no ordinary sense.

#### BOOKS, ETC., RECEIVED.

**Practical Diagnosis. The Use of Symptoms in the Diagnosis of Disease.** By Hobart Amory Hare, M. D., B. Sc., Professor of Therapeutics in Jefferson Medical College of Philadelphia, etc. Illustrated with One Hundred and Ninety-one Engravings and Thirteen Colored Plates. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. viii-17 to 573. [Price, \$4.75.]

**A Manual of Materia Medica and Pharmacology.** Comprising all Organic and Inorganic Drugs which are and have been Official in the United States Pharmacopœia, together with Important Allied Species and Useful Synthetics. Especially Designed for Students of Pharmacy and Medicine, as well as for Druggists, Pharmacists, and Physicians. By David M. R. Culbreth, Ph. G., M. D., Professor of Botany, Materia Medica, and Pharmacognosy in the Maryland College of Pharmacy. With Four Hundred and Forty-five Illustrations. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xi-17 to 818. [Price, \$4.75.]

**Food in Health and Disease.** By I. Burney Yeo, M. D., F. R. C. P., Examiner in Medicine at the Royal College of Physicians, etc. With Illustrations. New and Revised Edition. Philadelphia: Lea Brothers & Co., 1896. Pp. viii-592. [Price, \$2.50.]

**Index-Catalogue of the Library of the Surgeon-General's Office, United States Army.** Authors and Subjects. Second Series. Vol. I. A-Azzuri. 1896.

**Transactions of the Association of American Physicians.** Eleventh Session, held in Washington, D. C. Vol. XI.

**Die Infektions-Krankheiten. Ihre Abwehr und Unterdrückung.** Von Dr. Heurich Berger, königl. Kreisphysicus in Neustadt a. Rbge. (Hannover). Braunschweig: Friedrich Vieweg und Sohn, 1896. Pp. viii-3 to 310.

**Constipation. Some of its Effects, and its Non-medical Treatment.** By E. S. Pettyjohn, M. D., Alma, Michigan. [Reprinted from the *Journal of the American Medical Association*.]

**The Frequent Dependence of Insomnia, Mental Depression, and other Neurasthenic Symptoms upon Diseases of the Gastro-intestinal Tract.** By Boardman Reed, M. D., Atlantic City. [Reprinted from the *Journal of the American Medical Association*.]

**A New Spectacle Lens—A Compound Achromatic Periscope.** By F. Park Lewis, M. D., Buffalo. [Reprinted from the *Medical Record*.]

**The Parasitic Origin of Carcinoma.** By Charles F. Craig, M. D., Danbury, Connecticut. [Reprinted from the *Proceedings of the Connecticut Medical Society*.]

**A Report on Surgery and Nature's Antiseptics.** By J. Schwinn, M. D., Wheeling, West Virginia. [Reprinted from the *Transactions of the Medical Society of West Virginia*.]

**Eye Symptoms in Nephritis, as seen with the Ophthalmoscope.** By William Cheatham, M. D., Louisville. [Reprinted from the *American Practitioner and News*.]

**Anatomy, Descriptive and Surgical.** By Henry Gray, F. R. S., Fellow of the Royal College of Surgeons, etc. A New Edition, thoroughly revised by American Authorities from the Thirteenth English Edition. Edited by T. Pickering Pick, F. R. C. S. With Seven Hun-

dred and Seventy-two Illustrations, many of which are New. Philadelphia and New York: Lea Brothers and Company, 1896. Pp. 9 to 1249. [Price, \$8.]

**A Practical Treatise on Materia Medica and Therapeutics.** By Roberts Bartholow, M. A., M. D., LL. D., Professor Emeritus of Materia Medica, General Therapeutics, and Hygiene in the Jefferson Medical College of Philadelphia, etc. Ninth Edition, revised and enlarged. New York: D. Appleton & Co., 1896. Pp. xx-866.

**An American Text-book of Applied Therapeutics.** For the Use of Practitioners and Students. Edited by J. C. Wilson, M. D., Professor of the Practice of Medicine and of Clinical Medicine in the Jefferson Medical College, etc.; assisted by Augustus A. Eshner, M. D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. Philadelphia: W. B. Saunders, 1896. Pp. 5 to 1326. [Price, \$7.]

**A Handbook of Pathological Anatomy and Histology.** With an Introductory Section on Post-mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M. D., LL. D., Professor of the Practice of Medicine, College of Physicians and Surgeons, New York, etc., and T. Mitchell Prudden, M. D., Professor of Pathology and Director of the Laboratories of Histology, Pathology, and Bacteriology, College of Physicians and Surgeons, New York. Fifth Edition. Illustrated by Three Hundred and Sixty-five Wood Engravings printed in black and Colors. New York: William Wood & Co., 1896. Pp. viii-3 to 846.

**A Manual of Pharmacology and Therapeutics.** By William Murrell, M. D., F. R. C. P., Physician to and Lecturer on Pharmacology and Therapeutics at the Westminster Hospital, etc. Revised by Frederick A. Castle, M. D., etc. New York: William Wood & Co., 1896. Pp. vi-516.

**The Medical and Surgical Uses of Electricity.** By A. D. Rockwell, A. M., M. D., Fellow of the New York Academy of Medicine, etc. Illustrated with Two Hundred Engravings. New Edition. New York: William Wood & Co., 1896. Pp. xvi-612.

**A System of Surgery.** By Various Authors. Edited by Frederick Treves, F. R. C. S., Surgeon to and Lecturer on Surgery at the London Hospital, etc. Vol. II. With Two Colored Plates and Four Hundred and Eighty-seven Illustrations. Philadelphia: Lea Brothers & Co., 1896. Pp. xxiv-1120. [Price, \$8.]

**Functional Disorders of the Nervous System in Women.** By T. J. McGillicuddy, A. M., M. D., Consulting Physician to the Italian Hospital, New York, etc. Illustrated by Forty-five Wood Engravings and Two Chromolithographic Plates. New York: William Wood & Co., 1896. Pp. vi-367.

**A Pictorial Atlas of Skin Diseases and Syphilitic Affections.** In Photo-lithochromes from Models in the Museum of the Saint Louis Hospital, Paris. With Explanatory Woodcuts and Text, by Ernest Besnier, Physician to the Saint Louis Hospital; A. Fournier, Professor of the Faculty of Medicine; Tenneson, Physician to the Saint Louis Hospital; Hallopeau, Member of the Academy of Medicine, and Du Castel, Physician to the Saint Louis Hospital. With the Co-operation of Henri Feulard, Curator of the Museum, and L. Jacquet, Secretary of the Dermatological Society of France, etc. Edited and annotated by J. J. Pringle, M. B., F. R. C. P., Assistant Physician to and Physician to the Department for Diseases of the Skin at the Middlesex

Hospital, London. London: The Reiman Publishing Co., Ltd., and Philadelphia: W. B. Saunders, 1896.

A Vest-Pocket Medical Dictionary. By Albert Buck, M. D., New York. New York: William Wood & Co., 1896. Pp. vi 529.

The Tonic Treatment of Syphilis. By E. L. Keyes, A. M., M. D., Late Professor of Dermatology, Syphilology, and Genito-urinary Surgery, Bellevue Hospital Medical College, etc. Revised Edition. New York: D. Appleton & Co., 1896. Pp. x-78.

Röntgen Rays and Phenomena of the Anode and Cathode. Principles, Applications, and Theories. By Edward P. Thompson, M. E., E. E. Concluding Chapter by Professor William A. Anthony, formerly of Cornell University. Sixty Diagrams. Forty-five Half-tones. New York: D. Van Nostrand & Co., 1896. Pp. xiv-190.

Feeding in Early Infancy. By Arthur V. Meigs, M. D. Philadelphia: W. B. Saunders, 1896.

Transactions of the Medical Society of the State of West Virginia, June 10, 11, and 12, 1896.

Humane Society of the Commonwealth of Massachusetts. Report. 1895 and 1896.

The Treatment of Traumatic Lesions of the Kidney, with Tables of One Hundred and Fifty-five Cases. By W. Williams Keen, M. D. [Reprinted from the *Annals of Surgery*.]

Gangrene as a Complication and Sequel of the Continued Fevers, especially of Typhoid. By W. W. Keen, M. D. [Reprinted from the *Boston Medical and Surgical Journal*.]

The Technics of Abdominal Salpingo-oophorectomy without Pedicle. By T. J. Watkins, M. D., Chicago. [Reprinted from the *Medical News*.]

Induced Premature Labor. By J. G. Swayne, M. D., London. [Reprinted from the *Bristol Médico-chirurgical Journal*.]

A Case of Urticaria of the Conjunctiva. By S. M. Stocker, M. D., of Duluth, Minnesota. [Reprinted from the *Annals of Ophthalmology and Otology*.]

Prostitution—No License, but Prohibition. By G. Maxwell Christie, M. D., Philadelphia. [Reprinted from the *Hahnemannian Monthly*.]

## New Inventions, etc.

### AN ASEPTIC INJECTOR.

By WALTER F. CHAPPEL, M. D.,

SURGEON TO THE NEW YORK CITY, AIR, AND THROAT HOSPITAL.

SOME objection has been raised to the use of a cat's hair brush, as recommended by me, for the application of the new compound, oleostearate of zinc, to the nasal passages.

After considerable experimentation, the instrument shown in the illustration was suggested to me by Mr. William J. Evans. The construction is such that the medicine employed can not enter the rubber bulb, being prevented from doing so by the conoidal chamber, formed on the principle of a safety ink bottle, thus making the injector aseptic. The rubber bulb limits the amount of force used, which is always an important matter in nose and ear work.

The use of the injector is not confined to semi-

fluid preparations or to the nasal passages; in fact, any solution may be employed in it, and where a limited amount of force and fluid is needed, this injector is

available for any of the various mucous passages and also for eye and ear applications.

Directions for nasal use: Draw the fluid into the aseptic injector as you would into a medicine dropper; keep the rubber bulb upward and insert the glass tip into the nostril a short distance; then, tipping the head backward, hold the breath for a moment and press on the bulb. These directions apply to either nostril. When required for other purposes, suitable directions will suggest themselves to the physician.

## Miscellany.

**Poisoning with Scopolamine.**—In the *Medical News* for September 12th the following case is related by Dr. Matthias L. Foster:

A young laboring man, who had been treated for a considerable time for a mild form of trachoma, was found to be astigmatic, and it was decided to be advisable to examine him under the influence of a mydriatic. Scopolamine was chosen, and four instillations of one drop of a fifth-of-one-per-cent. solution were made in each eye at intervals of ten minutes, commencing at 8 p. m. Fifteen minutes after the last instillation, a little over an hour after the first, the patient complained of dizziness, and was obliged to lie down. This was followed by dryness of the throat, nausea and attempts to vomit, flushing of the face, decrease in the strength, and increase in the rapidity of the pulse, symptoms which increased with alarming rapidity for half an hour, and reached their culmination in about two hours. At the end of half an hour the pulse was over 160 a minute and very weak, the face was growing darker until it became mildly cyanotic, the patient was unconscious and wildly delirious. The muscles of the extremities were frequently and strongly convulsed. When at the worst it took the strength of several men to hold him, and some doubt was expressed by the gentlemen gathered about him whether his struggles were the result of the active delirium which was present or spasmodic contractions of the muscles from the irritation of the drug. The pharyngeal muscles appeared to be in a state of paresis.

These symptoms began to abate in about two hours under energetic treatment with morphine and whisky, and the improvement progressed so rapidly that the patient was able to leave the hospital and walk home at 6 a. m., ten hours after the first drop was instilled. Nausea and dizziness persisted for a day longer. The recovery from the mydriasis was in the usual time.

It should not be inferred from such a history as this, says Dr. Foster, that scopolamine is too dangerous a drug to use, but it should be understood that it is too dangerous a drug to use without proper care and precaution. Certain individuals, he says, are, without doubt, more susceptible to its influence than others, and the rapidity of its action suggests a way in which it may be possible to avoid giving an overdose. The observations in regard to its effect on the ciliary muscle show that the time necessary for complete paralysis varies from ten to sixty minutes, and that the quantity of solution of the usual strength required to produce this effect is from one to five drops; hence it is wise to test the accommodation before the second and all succeeding instillations, to avoid the unnecessary use of the drug after the ciliary paralysis is complete. Another practical precautionary measure is to occlude the tear-ducts by means of pressure by the patient's finger as soon as a drop has been instilled into the conjunctival sac. This prevents the passage of the solution through the lacrymal passages into the nose and its absorption through the mucous membrane. When these two precautions are observed the danger of poisoning is reduced to a minimum.

**Canine Rabies in India.**—Mr. J. C. Vaughan, of West Bengal, contributes a paper on this subject to the *Indian Medical Gazette* for August in which he gives a detailed account of his experiences with rabies in his own dogs, the main points of which are as follows: In every case, he says, the first thing which aroused his suspicions was an excess of freshness, a greater display than usual of affection for their master, and a somewhat increased display of vigor and vitality in all they did, although combined, perhaps, with a slight nervous excitability; but there was no irritability or snapping at other dogs. There was, perhaps, a tendency to bark too much for no ostensible reason. The preliminary catarrh of which the veterinary surgeon, Mr. Martin, speaks did not occur in these dogs. The suspicious symptoms never proved to be a false alarm in the author's experience. The excitability showed a steady tendency to increase, and within twenty-four hours the dogs' eyes became dull and there was a half-dragged far-away expression in the face and eyes which was strangely out of keeping with the still restless and excitable manner. At this stage the food was eaten with increased greed and haste; there was still the curious isolated, purposeless bark, which was distinctly changed from the sound of the full bark. This voice condition was the first symptom of the weakening of the muscular innervation of the pharyngo-laryngeal region which, says the author, is so distinctive of hydrophobia. At this time also a frequent movement of the tongue was noticed. Gradually the excited manner quieted down, although occasionally the old excitement broke out and the eyes flashed with a dull light. In the next period of the affection there were tremors of the limbs, subsultus tendinum of all the legs, and a quivering in the lower jaw; there was a troubled sleep from which the dogs awoke more restless than ever. They were now quite mad, says Mr. Vaughan. The excitability, which had returned, the dull look in the eyes, the dilated pupils, the staring coat, and the slight stagger of the hind quarters which had set in, made up a picture which it was impossible to mistake. The dogs refused solid food, the temperature rose, the urine was high colored, and the faeces were almost black. Though they were still docile,

continues Mr. Vaughan, and glad to receive their master or visitors with expressions of affection, it was at this time that they became uncertain.

In this condition, he says, their jaws may snap together in the excited affection they show and they bite without meaning to. From this time they seem gradually to lose self-control and become more and more dangerous. Even at their very worst, the author states that his dogs never altogether lost their self-control, and that he was able to go up to them, carefully gloved, and pat them, and, although they snapped their jaws at him, it was unintentional, as their manner showed. The paralysis of the hind quarters and of the pharyngo-laryngeal region increases at this stage, and the period of excitement passes more or less quickly into one of deepening stupor from which there are often convulsive awakenings; the intervals between these grow longer, and finally death ensues.

The author states that he watched these cases very carefully to the end, and it is very clear, he thinks, that the disease described is the form known as furious rabies. Dumb rabies begins very much in the same way: the restless sleep seems to be the turning point, and the dog wakes up paralyzed, with dumb rabies or the furious form. A very dangerous period in the disease, Mr. Vaughan thinks, is the preliminary stage, just before the expression changes, for the nature of the case is then so hard to recognize.

A very important point is the question of the immediate treatment of bites from rabid dogs or doubtful ones. The author has always practised washing the wound freely at once and then burning it, not with solid silver nitrate, as is the usual way, but with strong fuming nitric acid or with strong hydrochloric acid. Even in the case of bites from rabid dogs this plan, he states, has effectually prevented hydrophobia. This treatment was carried out in the case of a relative of the author, who was bitten by a rabid dog twenty-four years ago, with a successful result, for the man is still living. On one occasion several dogs were bitten by a rabid dog; this treatment was at once instituted and none of the dogs died of hydrophobia. Mr. Vaughan thinks that the same trust can not be placed in nitrate of silver for the following reason: When it is a question of a deep bite from the long canine fang of a dog, the tooth, which is a blunt instrument, has been driven by main force through the skin into the tissues, and, when so driven in, was coated with the poison-containing saliva, which was forced into the intercellular spaces of the tissue penetrated by the tooth, and although some of it lies in the wound cavity or lines the edges of the wound cavity inside, some or most of it has been jammed into the intercellular spaces around that cavity, and lies deeper in the tissues. The wound cavity in the mean time is filled with and its sides moistened with serum containing albumin. The nitrate-of-silver stick now penetrates into the wound cavity, reaches the saliva and serum lining its sides, kills the lining cells, and coagulates all the albumin within reach. The albumin film thus formed makes, no doubt, says the author, a film which only protects the deeper-lying saliva and its poison; and in a deep penetrating bite forcing in a stick of nitrate of silver is very much like repeating the bite, and serves to drive the deeper-lying saliva only deeper still into the tissues and so to place it farther outside; hence better protected by the albumin-coagulum film formed in the wound by the nitrate-of-silver treatment. If no albumin was coagulated in the wound, the caustic

would or might reach the farthest off and most deeply lying saliva. But, as nitrate of silver forms an albumin coagulum, why not use, asks the author, an equally strong caustic which forms no coagulum? Hence the use of the fuming acid, which dissolves all albumin it reaches, and penetrates at once without the use of force into all the surrounding tissue spaces. The same holds good for all kinds of bites, and the penetrating acid kills all it reaches. One or two drops suffice for each bite, the slough soon separates, and the clean wound then left heals readily. Mr. Vaughan states that he has treated a great many bites in this way, and when his own dogs went mad he has invariably found that they had been bitten while he was away from home.

For the preceding reasons he says that he has always strongly objected to cauterizing any bites with nitrate of silver, and has invariably advocated the use of strong acid. But whatever the immediate treatment is, it must be prompt.

**Subcutaneous and Intravenous Saline Injections.**—At a recent meeting of the Congrès français de médecine interne, a report of which is published in the *Indépendance médicale* for September 9th, M. Vedel called attention to his investigations and the results of his experiments with injections of saline solutions. He had experimented on dogs with the simple saline solution after infection by intravenous injection of the *Bacillus coli* cultures, which causes rapid death and is accompanied by hemorrhages and gastro-intestinal troubles; the heart is very weak, the blood pressure is considerably lowered, diuresis is suppressed, and there is an elevation of temperature followed by hypothermia.

If the intravenous injection of serum is made during or immediately after the inoculation, the evolution of the disease is slower, and the general troubles are less pronounced. Recovery may be produced by several successive injections. If the infection is not intense, an early injection may even prevent the development of the infectious symptoms. A delay, even slight, in administering the saline injection after the inoculation does not give so favorable results, although recovery may still be possible. The consecutive injections are a great aid to the first one. After the first tardy injection there is a slight amelioration of the pulse, but it is impossible to arrest the hypothermia and the weakness of the heart. Then, an infected organism does not tolerate so well very large injections, which disorder the heart, with asphyxia, a comatose condition, convulsions consecutive to a peritoneal effusion, to a pulmonary hemorrhagic edema, and to effusions beneath the pia mater.

Doses of from twenty-five to thirty cubic centimetres a kilogramme, given as rapidly as from thirty to forty cubic centimetres a minute, have no injurious action, and generally from two to four doses bring about recovery. The first injection must be administered as soon as possible after the inoculation in order to obtain the greatest chances of recovery. As to the successive injections, the condition of the heart, of the temperature, and of diuresis it must be ascertained first. In making the prognosis it must be borne in mind that the reactional effects diminish after the first injections when recovery is to take place. If the diminution of the functional reactions is caused by the insufficiency of the injections, a progressive development of the infectious symptoms in an inverse direction will be witnessed.

M. Vedel states that he has made large injections as follows: In cholera, which perhaps is similar to *Ba-*

*illus coli* infection, there was jugulation. During the injection the general condition became ameliorated, the pulse grew more energetic, while intermittence was suppressed, the blood pressure was heightened, respiration was better, and the temperature rose. These effects were maintained for thirty or forty minutes; then the critical period of reaction set in; a violent chill supervened; the pulse was frequent and uneven, respiration was accelerated, there were spasms, and there was a rapid elevation of the central and peripheral temperature. At this stage the cold was followed by heat, the face became gaunt, the conjunctivæ were injected, respiration was painful, the pulse was accelerated, and the tendinous reflexes were exaggerated. This condition lasted about four hours and was accompanied by micturition, diarrhoea, and sweating; afterward the condition ameliorated and recovery took place, whether preceded or not by other reactions.

In a case of migratory pneumonia of the apex, accompanied with adynamia, in an alcoholic subject, in which the temperature had been elevated for ten days, the intravenous injection gave rise to the same symptoms. At the end of several hours the temperature, which had risen to 104.2°, fell to 96.6° F., and became normal after a few slight oscillations. In this case it was not a natural crisis provoked by the injection. In two cases of staphylococic infection with a disseminated purulent focus and a fever which varied greatly, the intravenous injections produced again the same general effects. The injection was not followed immediately by recovery by normal fixation, but there was an amelioration of the general condition, and the patients eventually were cured.

The injections, said M. Vedel, then brought about a true critical movement which was capable, in acute infections, of causing the immediate victory of the organism, and, in infections of slow evolution, with purulent foci, of restoring the strength, the heart, and especially the general nutrition, and of increasing the force of resistance. In the infectious diseases saline intravenous injections may always be administered. But they must be practised as soon as possible after the beginning of the infection, and the important indications must be looked for in the state of the pulse, of the blood pressure, of diuresis, and of the general condition.

Anuria and albuminuria are not contraindications of these injections. However, there are no contraindications, and accidents are impossible in the conditions laid down by the author. If the kidneys are profoundly and irremediably affected, strong doses must not be administered; also, if there is pulmonary edema, the injection must be graduated in case of an affection likely to cause hemorrhages, like the *Bacillus coli* infection, in order not to favor the very tendencies of the infection.

#### Conditions which may Simulate Organic Obstruction of the Large Intestine.

—The following is an abstract of a paper presented at the recent meeting of the Mississippi Valley Medical Association by Dr. Thomas H. Manley, of New York. The large intestine in any part, from the ileo-cæcal junction to the anal outlet, is liable to obstruction in varying degrees in its various segments. As the anatomical distinction between the large and the small intestine is very wide, and as they are altogether dissimilar in function, it necessarily follows that both the etiology and the symptoms of stenosis in either one should bear but little analogy to the other.

The small intestine is rich in smooth muscle and

adenoid elements, is richly supplied with non-medullated nerves from the sympathetic system, has a long free mesentery, is the centre of action of peristaltic movements, and, exclusive of the duodenum, is entirely within the peritoneal cavity. This is the centre of active, vital, and chemico-physical changes in digestion.

The large intestine, on the contrary, is little more than a sewer-vent to receive, lodge, and discharge the residual detritus of digestion. It contains but little muscular fibre in its sacculated cylinder, but is strongly braced by dense bands of fibrous tissue. The inner coat is made up chiefly of mucous glands, and the lumen of the bowel is of quite constant dimensions. This part of the alimentary canal is more or less fixed, permitting of but a moderate range of motion. The large intestine is but imperfectly invested by peritonæum, and the rectum is almost entirely outside this membrane. The position, shape, and arrangement of the colon favor many pathological processes in the human being.

In function, this elongated, arched, and flexed coil serves a similar purpose to that of the bladder, as a pouch for excrement; vastly more complicated, it would seem, than its purposes require. The healthy mucous membrane of the bladder is proof against the absorption of non-corrosive poisons in solution, while the rectal end of the large intestine absorbs almost any substance in a soluble state; and, in cases of impaction, or fæcal stasis, we have reason to believe that the large intestine resorbs many of the most lethal elements of its own contents.

Probably there is no organ in the body more subject to atypical deviation in development and in its relations than the colon. This is particularly manifest to the surgeon in operations on its cæcal end, as has been ably dwelt on in an essay by Dr. Theodore A. McGraw, of Detroit, on *The Surgery of the Large Intestine*.

In the human subject the alvine current must ascend against gravity, make various detours as it clears the colic valve, course around three sharp angles, and pass the double flexures in the sigmoid, before it is discharged into the rectum preliminary to expulsion.

The segments of the colon liable to displacement and inclusion in hernia are: 1, the cæcum and appendix; 2, the transverse colon in umbilical hernia; 3, the sigmoid flexure. The third is the rarest, although a case came under my notice this summer (1896) in a young gentleman brought to me by Dr. J. B. Cowan, of Radford, Virginia, who had been treated for stricture of the rectum. There was found no rectal stricture, but a partial escape of the sigmoid, which, when caught in the inguinal rings, would give rise to symptoms of rectal obstruction. I have met with the cæcum in operations for strangulated and irreducible inguinal hernia. In a large umbilical hernia the transverse colon is frequently engaged.

In my own experience in this type of extrusions, either in inflamed, incarcerated, or strangulated hernia, the symptoms of collapse do not set in so early as when the small intestine is involved.

*Sex and physiological condition* play an important rôle in the ætiology of pathological conditions in the rectal end of the large intestine. A careful study of the radical difference of the anatomy and the functions of the organs near the pelvic outlet will readily convince one of this. The genital organs here come into play as a prominent factor. In the male of advanced years, an hypertrophied prostate may press steadily on the rectal ampulla, provoking an irritation and, in aggravated

cases, acting as a barrier to defecation, thus inducing symptoms of obstruction. It is in the female, however, that the influence of genital ectopia or fæcal impaction of the rectum is most pronounced. Here the pelvic genitalia and the crippled rectum act on each other. A retroverted, enlarged uterus may so encroach on the anterior wall of the rectum as to quite close its lumen, excite a proctitis and tenesmus, or even give rise to such a condition as to lead the unwary to suspect a neoplasm of the rectum. This actually occurred in two cases which have come under my notice, in each of which the uterine body, crowding against the rectum, led to the opinion that a tumor had formed in its walls. In each a pessary relieved all the symptoms. At the present time an elderly lady who is under my care with an incurable procidentia suffers all her distress from rectal symptoms. And *per contra*, how many women there are, tentatively treated for various uterine and vesical disorders, whose entire troubles depend on either cæcal, sigmoid, or rectal impaction!

Intestinal obstruction of various degrees occurs at any stage of life, but in the large intestine, if we exclude intussusception—a condition peculiar to early life—we rarely encounter it until the vital forces commence to fail and degenerative changes begin, when the teeth have fallen out and the glands have diminished in activity. Mechanical obstruction in the large bowel depends on influences of two orders—the intrinsic or organic, and the extrinsic or indirect; the latter only will be briefly considered here. This may be complete or incomplete. It develops in consequence of (a) inertia or atony of the intestine with fæcal impaction; (b) ectopia of adjacent organs, or morbid growths of structure, second in order of frequency; (c) hernia of various types—the rarest, most acute, and most dangerous. The immediate danger to life from impediment in the large intestine, except in hernia, is not great; in the chronic form, the constitution is undermined by conditions consecutive to colic stasis.

In the rectum we find the most palpable evidence of pathological changes; first, in their degenerative vascular changes so generally met with here, especially in the childbearing woman; and, secondly, in the damage to the levator ani, a muscle which serves a complex purpose in her sex. At the anal verge and just above it we may find a dense hypertrophy of the submucous tissue encircling the entire bowel. This may or may not prolapse in defecation, but, at all events, it often serves as an impediment to evacuation or a complete clearing of the rectum. In a recent case in which I operated it produced so many symptoms of obstruction that a stricture was suspected by the physician who sent the patient to me.

In women after the menopause the pelvic organs undergo atrophic changes which seem to extend to the rectal structures, for in many, late in life, moderate impaction of the rectum is very general, and it is by no means uncommon in elderly men who neglect their regular evacuations or are prone to degenerative lesions of the spinal cord, such, especially, as involve the trophic or sensory nerves.

*Hernial protrusion* often comes late in life, or but a small unnoticed rupture has existed, to give trouble later. A young man came under my care some years ago in a sad state from hernial gangrene. He had had a swelling in the right groin for several months. He did nothing for it until it finally began to give him pain. Then he went the rounds of the dispensaries,

and it was repeatedly poulticed. After a time it broke through the skin; the displaced cecum had ruptured in a rotten, gangrenous state and had allowed the feces to escape through the new opening. An error in diagnosis had been committed and a life lost. As some individuals go for weeks without a full motion from the bowels, they may deceive the physician by not mentioning this when they come under his care.

Massive tumors, the pregnant uterus, and a displaced kidney may all interfere with full colic action and lead to symptoms of obstruction.

The symptoms which attend rectal or colic obstruction are local and general. In partial or complete obstruction of the large intestine, the dominant symptoms are local. One patient is constive; he thinks he has "piles" or vesical disease, from pressure on the bladder, as occurred in one of my own, a gentleman from whom I removed a massive rectal enterolith as large as a foetal head, which had to be split and removed in sections. It was most remarkable that the patient was entirely unconscious of its presence, though he had severe troublesome vesical symptoms. For fourteen years his bowels had moved only when his valet gave him enemas. He assured me that he was confident the petrified mass had been lodged there fourteen years, and in this view his son, who is a physician, concurred.

In diagnosis the most frequent lesion liable to be confounded with extrinsic obstruction of the large intestine is cancer. This dreadful malady works great havoc here. According to Sutton, ninety-eight per cent. of cancers of the bowels occur in the large intestine—namely, seventy-five per cent. in the rectum, ten per cent. in the sigmoid, four per cent. in the splenic flexure, three per cent. in the hepatic flexure, two per cent. in the cecum, and four per cent. not specified.

We endeavor to make a diagnosis in this class of cases by surface and rectal explorations. In persons who are not too fat much valuable information may be elicited by abdominal examination, by percussion and posture of the body. It will answer in most cases of cæcal or sigmoid impaction, alone or conjoined with bimanual manipulation. In acute cases, we should always institute a most thorough search for hernia and not be content with inspection, but test all suspected portals of escape by the tactile sense.

Rectal examination is the most positive and valuable in its results as a diagnostic resource. In all suspected cases, this should be insisted on. One patient may insist that his bowels are "loose" or that he completely evacuates them, when neither is the case. Sensation is blunted, and he unconsciously deceives himself. This examination is of most importance in women, on whom it may usually be made most complete. It entails practically no exposure, and with few exceptions is quite painless. The type of alvine obstruction here considered, excluding that induced by hernia, should never of itself seriously threaten life. It only needs to be definitely recognized to be safely and permanently relieved.

**The Serum Treatment of Cancer.**—At a recent meeting of the *Congrès français de médecine interne*, a report of which appears in the *Gazette médicale de Paris* for August 29th, M. Dubois stated that he had introduced fragments of cancers taken from human subjects into the cellular tissue of animals and had obtained several tumors, the largest of which weighed between seventeen and eighteen ounces. The serum of these inoculated animals was then employed in three cases of

cancer. In the first case there was non-ulcerative cancer of the breast in which the treatment led to an almost complete recovery after a period of forty-five days. The second case was one of epithelioma of the face, which subsided in thirty-nine days. In each case from two to five cubic centimetres of the serum had been injected in the region of the tumor every three days, and a few drops of alcohol with a very small quantity of iodine had been injected around the tumor in the second case. The third case was one of relapsing epithelioma of the upper lip, which was very much ulcerated and highly inflamed, and after twenty-three days of the treatment the progress of the tumor seemed to have been arrested, but it presented no tendency to complete recovery. From these facts M. Dubois concluded that the serum of animals inoculated with cancerous elements seemed to cure cancer by fibrous transformation. Its action was much more certain, he said, when it was employed in the beginning of the disease. He thought its employment presented no dangers, except in cases of extensive lesions.

M. Bard stated that he did not believe that the tumors which were obtained in the animals by inoculation were of a really cancerous nature; he thought that they were simply of an inflammatory nature and not true neoplasms. The local reaction produced in the animals did not prove that they had been influenced by the inoculated cancerous elements. Furthermore, he thought that the alcohol and iodine which had been employed in the second case might have had a local action which diminished that of the serum. Moreover, serum injections in the region of a tumor caused, in some cases, a local inflammation which was sometimes useful; therefore he did not consider M. Dubois's experiments conclusive.

#### **The Treatment of Inflammation of the Milk-ducts.**—

In the *Gazette de gynécologie* for August 15th M. Brindeau remarks that, as this disease is caused by an infection which attacks the external orifice of the ducts, its production may be arrested to a certain degree by prophylactic measures. The patient should be directed not to touch the affected region any more than possible, and told that before and after nursing she should carefully wash the nipple with warm boracic acid water. Finally, a dressing should be kept on the breast. If the child presents any suppurative whatever, and especially conjunctivitis, the diseased region should be isolated by means of a protective dressing.

When the affection is observed, says the author, the treatment recommended by M. Budin should be resorted to, as it gives excellent results. It consists in the evacuation of the pus by digital pressure, which should be done in a certain way. At first the ampullæ of the galactophorous canals are emptied. To do this, the thumb and the index finger are applied to the outer part of the areola, then strong pressure is brought to bear from before backward, and from the surface toward the depth; the two fingers are then brought nearer together while continuing the pressure up to the nipple. This causes the expulsion of the pus and of the milk also. This procedure is practised on different parts until the pus ceases to discharge. If the infection has invaded a lobe, it should be subjected to pressure from without inward in such a manner as to draw the pus back into the galactophorous canal, which is then emptied in the manner previously indicated. After this procedure the breast is washed with a slightly antiseptic

liquid and then it is compressed and held up firmly. This procedure, says M. Brindeau, has the twofold advantage of influencing the disease and preventing the patient from nursing with the diseased breast. Infants should not, in fact, nurse from a diseased breast under any pretext. The dressing should be withdrawn at night in order to repeat the treatment, which should be continued until no pus remains in the gland. It is advisable to allow an interval of two or three days to pass before the child is permitted to nurse. If lymphangitis exists at the same time, the treatment is the same, but it is much more painful, and, in certain cases, it is better to administer a little chloroform to the patient. The lymphangitis is to be treated with hot spraying and moist dressings. If an abscess forms in spite of the treatment, a large incision of the sac should be made. If the child continues to nurse from the healthy breast, and if the quantity of milk is insufficient, sterilized milk may be given.

#### **Pyrozone and Dilute Hydrochloric Acid in the Treatment of Suppurating Inflammations of the Middle Ear.**

—In the *Medical Record* for September 12th, Dr. William Cheatham calls attention to a line of treatment which, he says, has rendered him the best service in two cases of this most obstinate affection. In both cases the curette, chromic acid, pyrozone, formalin, boric acid, and many other remedies were employed, but no permanent relief was obtained. Finally the author directed that ten drops of a mixture of ten drops of dilute hydrochloric acid and an ounce of pyrozone should be put into the ear three times a day after cleansing it; the mixture was to be left in for five minutes after having been forced in deep by firm pressure upon the tragus. In the first case a remarkable change was noticed in a few days, and in a short time there was no secretion from the cavity, and there has been no return of it for several months. In the second case the patient began to improve rapidly in a few weeks, and recovery set in with no relapse.

Dr. Cheatham states that he has treated several similar cases with but one failure, and that occurred in a tuberculous subject. He has treated many cases of less severity with only an occasional failure, and he has not seen this treatment fail in acute cases. Of course in the primary stage of acute cases, he says, such medication is contraindicated, but after pain, throbbing, and swelling have subsided, and suppuration continues, notwithstanding ordinary treatment, the acid and pyrozone check it very promptly.

As to drainage in these cases, he says, the iodoform or some other of the gauzes cut into narrow strips has given him by far the best results.

This treatment is not a cure-all by any means, continues Dr. Cheatham, but he hopes this brief report will lead others to try the acid-and-pyrozone combination. Of course, when the deeper sinuses are involved surgery is first indicated, then the pyrozone and acid. Under its use he states that he finds mastoid-cell involvement much less frequent, and that he does not believe these effervescing preparations increase such dangers.

**The Employment of Turpentine Baths.**—A writer in the *Journal des praticiens* for August 29th states that these baths have been employed in the treatment of simple articular rheumatism by Dr. Smith and Dr. Howard Pinkney, of New York. The latter even recommends them for gout and eruptive fevers. M. Balzer was the first to use them in the treatment of blennor-

rhagic rheumatism, and obtained excellent results. The following formula is recommended by Dr. Smith:

Oil of turpentine.....	3 ounces;
Oil of rosemary.....	150 grains;
Sodium carbonate.....	15 ounces;
Water.....	30 ounces.

M. Balzer's formula is as follows:

Aqueous emulsion of black soap,	each, 3 ounces.
Oil of turpentine,	

These baths are to be employed under two forms, general and local. The former is indicated when several articulations are affected or when the situation of the diseased joint is incompatible with a local bath. Quantities varying from four ounces and a half to fifteen ounces and even twenty-two ounces of the turpentine mixture may be employed, according to the susceptibility of the patient's skin, for the baths produce a pronounced burning sensation. The medium amount is twelve ounces. The bath should be prescribed as soon as possible, and the temperature should be gradually increased until it reaches 104° or 107.3° F., provided the patient does not complain. The bath may last from ten to twenty minutes. Some inconveniences may be noticed, such as a burning sensation of the skin of the genital organs, but this may be avoided by covering the parts with a greasy substance.

Local baths, says the writer, are preferable, and should be resorted to, if possible, in all cases. From an ounce and a half to three ounces of Balzer's mixture is put into the bath and the temperature raised to 122° F. if the patient can bear it. Local and general baths may be alternated.

There are certain precautions to be taken in connection with this treatment. It must not be employed until the acute symptoms have disappeared and the temperature has fallen, and the susceptibility of the patient must be ascertained. The effects are constant and consist in a rather sharp burning accompanied by a pricking sensation; at the end of fifteen minutes the skin is hot and completely red. The pain is immediately relieved while the patient is in the bath, and this relief persists afterward for two or three hours.

**Carbuncle treated with Zinc Chloride, Boric Acid, and Iodoform.**—Assistant Surgeon P. Victor, of Khulna, relates the following case in the *Indian Medical Record* for August 16th: The patient, a man forty-five years old, suffered from a huge carbuncle on his back; it measured twelve inches in length and seven inches in width. There was oozing of pus from several small openings. As the patient was too weak and exhausted, and had a temperature of 102° F., the author refrained from placing him under the influence of chloroform at once, and making a free incision, and scraping. He therefore ordered a large carbon poultice to be applied every four hours, which broke down the skin and showed a very large gaping wound with sloughs in abundance. The wound was thoroughly washed with antiseptic lotion, and the entire surface brushed with a solution containing four grains of zinc chloride to an ounce of water. It was then dusted with equal parts of boric acid and iodoform, and dressed with antiseptic gauze. As the discharge was very profuse, the dressings became saturated, so the carbuncle was dressed daily and brushed with the zinc chloride solution every second day. On the eighth day the fever abated, and on the ninth day the wound was clear of all sloughs, and looked healthy and granulating.

On the twentieth day after the patient's admission to the hospital the wound was healthy and smaller, having diminished to eight inches in length and three inches in width. The patient's condition was much improved, as he had been kept on a nourishing diet with liquor carnis one drachm every four hours, and a mixture of bark and ammonia thrice daily. The exuberant granulations were kept down by an occasional touch of sulphate of copper and the wound dressed with the red lotion, two grains of zinc sulphate, twenty minims of tincture of lavender, and an ounce of water.

The patient was discharged cured on the 19th of July. The knife was quite dispensed with, says the author, and with the help of the zinc-chloride solution and strict antiseptic dressing the patient made a good recovery. The urine was free from sugar and no diabetic symptoms were present.

**Virol.**—The *Indian Lancet* for August 16th says that three years ago the Liquor Carnis Company introduced bone-marrow as a food for invalids in the form of virol, and that since then great improvements have been made in the process of manufacture and in the preparation itself. Originally the manufacturers intended virol to be a palatable substitute for cod-liver oil, but it has been thought to be useful as a fat food for infants and young children, and it is now used very largely in a great many children's hospitals and also by the public. It has an advantage over milk, as it contains iron, and it also possesses an advantage over nearly all the advertised infant's foods, inasmuch as it contains free fat which is strongly urged in the diet of infants by Dr. Fothergill and Dr. Cheadle.

**Serum in the Treatment of Mental and Nervous Diseases.**—At a recent meeting of the Congrès français de médecine, a report of which appears in the *Progrès médical* for September 5th, M. Monret and M. Vires stated that they had injected the serum taken from a maniac who had recovered into two others who were at the height of maniacal excitement. To the first patient three injections of ten cubic centimetres each were given at intervals of two or three days during the period of agitation. The injections were followed by a condition of apathy and somnolence, but twelve hours afterward this condition disappeared and a fresh attack occurred. The second patient, after the injection, fell into a deep sleep, but gradually his mental and physical condition became ameliorated, and, finally, he left the hospital cured.

The authors thought that these injections had exercised a favorable influence in promoting the recovery of the patient. At any rate, they drew the following conclusions: 1. That the blood serum of a convalescent injected into a patient was harmless, either locally or in regard to the general nutrition. 2. That the hygienic effects of this serum were very distinct and very profound.

**A Peculiar Symptom of Dry Pleurisy.**—The *Indépendance médicale* for September 2d publishes a report of a recent meeting of the Congrès de Nancy, at which M. de Langenhagen related the case of a tuberculous arthritic patient in whom there was a limited lesion at the right apex which appeared to be arrested. Several times during one winter the patient had an attack of dry pleurisy which was situated very near the diaphragm at a distance from the tuberculous region, which re-

mained dormant. One of the attacks occurred in the diaphragmatic pleura. The author observed then frequent eructations, each one of which was accompanied by a very sharp pain which extended far under the median line, along the œsophagus, and laterally toward the right attachments of the diaphragm.

This peculiar and violent pain persisted for several days, as well as the dyspnea and the other symptoms, but it diminished, as they did, under the influence of morphia.

This painful sensation was, said the author, no doubt, connected with the passage of the gases which were suddenly forced back by regurgitation from the stomach. These gases distended the œsophagus, which, subjected to an abnormal pressure, caused a deviation of the posterior pillars of the diaphragm, the contractions of which were communicated to the phrenic centre, to the anterior insertions of the muscle, and these insertions, through their connection with the diseased pleura, became irritated.

This pain, the author thought, was analogous to the pain which occurred on deglutition, which was sometimes observed in intense pleural effusions. Both were of mechanical origin, and were produced by a gaseous pressure in cases of dry pleurisy.

**A Remedy for Stage-fright.**—The *Lyon médical* for September 6th states that, according to the *Médecine moderne* for August 22d, an American physician advises students to combat the nervous asthenia which paralyzes their faculties and causes them to lose the thread of their ideas by taking ten drops of tincture of gelsemium three times a day. For the same purpose an English specialist prescribes wine of opium to be taken by actors and singers before going on the stage. From five to six drops, he says, will give to the most timid actress the self-possession of the most spirited old player.

**Medicinal Treatment of Irritable Temper.**—In the September number of the *Glasgow Medical Journal* there is an abstract of an article from the July number of the *Practitioner* in which the writer says that Dr. Lauder Brunton has paid some attention to the subject of bad temper as an indication of diseased conditions, and to the method by which relief of a symptom so personally and socially distressing can be obtained. Some time ago he noted that unwanted irritability of temper was often the precursor of a headache, and described the beneficial action of bromide of potassium and salicylate of sodium in relieving the headache. He now recommends the same combination for irritability of temper occurring in connection with various diseases, and more especially in gout and heart disease. The beneficial effect of the bromide upon the irritable nerve centres is, of course, universally recognized, and Dr. Brunton considers that the researches of Dr. Alexander Haig justify the conclusion that the salicylate of sodium is of value by promoting the elimination of uric acid. Referring to irritability of temper as a symptom of cardiac disease, Dr. Brunton remarks upon its frequency, and quotes the case of a child in whom it was the only symptom of mitral regurgitation, the physical evidence of the disease being observed almost by accident. He finds the above-mentioned remedies to be valuable adjuncts to the use of digitalis and other cardiac tonics. They improve the subjective condition of the patient, and thus facilitate his recognition of improvement.

## Lectures and Addresses.

### LECTURES ON ANGINA PECTORIS AND ALLIED STATES.

By WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

#### LECTURE V.—PSEUDO-ANGINA PECTORIS.

(Concluded from page 411.)

HYSTERICAL angina in the male is usually a very well-characterized affection. The following cases are the most typical which I have seen:

CASE V.—W. H., seen with Dr. Purvis, of Alexandria, aged thirty-two years, complaining of severe attacks of pain about the heart.

The patient comes of excellent German stock. His mother is alive and his brothers and sisters are well and strong; there are no special nervous troubles in the family. Though an hotel-keeper he has been very abstemious in the use of alcohol. He has never had syphilis. He has been nervous from boyhood. When about fifteen he had a fright, after which he had nervous spells, called fits, for several years. From his description, they were evidently severe hysterical attacks. At the age of twenty-three he had scarlet fever and diphtheria, and nearly lost his life. For the past six years he has had a great deal of mental worry, and for nearly two years a good deal of extra financial strain. During this time he has had at intervals what he calls nervous attacks. He would get numb in his feet and then in his legs, and a sensation would rise in his body like a wave, making him cold and faint.

Dr. Purvis, who has seen him in the spells, says they are evidently hysterical. He does not lose consciousness.

For the past three months he has had different attacks, consisting of very agonizing pain about the heart, extending to the shoulders and down the arm even to the fingers, very frequently only to the index finger and thumb of the left hand. They have come on most frequently while walking. He catches his breath and has frequently had to sit down on a doorstep. He describes the pain as very agonizing, but he makes no mention of any sensation like that of impending death. His hands get cold; sometimes the feet are cold, and he has at times broken out into a profuse perspiration. The attacks have recurred with great frequency. He has had as many as four in the twenty-four hours. Worry, over-exertion, and on several occasions a full meal, have caused attacks. They have increased rather than diminished during the past month.

The patient was a healthy-looking, well-nourished man, of good color, of fair physique, with black hair and eyes. The pulse was quiet (80 a minute), tension not increased. He flushed easily, and there was the most marked factitious urticaria and dermatographia. The apex beat was not visible and not palpable. The superficial cardiac dullness was not increased. The sounds at the apex were clear. There was no accentuation of the aortic second, and there were no murmurs. There were no painful spots about the præcordia. The patient subsequently entered the private ward of the hospital, where he had several attacks of the character above described.

CASE VI.—On May 23d I saw at the Rennett Hotel,

Dr. R., aged thirty-three years, a physician from one of the Northern cities, who had had a series of most severe attacks dating from May 15th.

The patient, a man of very high-strung, nervous organization, had had a very hard battle in life, overcoming almost insuperable physical difficulties. His general health had been very good. He had been a very hard student, and had done much work outside his ordinary professional duties. Three years ago, while engaged in instructing a class, he felt suddenly a terrible pain in the heart, and a numbness extended down the left arm and leg. He was unable to stand, but did not lose consciousness. He recovered from this attack in the course of an hour or so, and had no recurrence until the 15th of the present month. At 5.30 P. M., while in a cab, he was suddenly seized with an agonizing pain just below the left nipple. There were numbness and tingling in the left arm and leg. That night the pains recurred, and from his wife's account he evidently had a series of hysterical attacks; he became very emotional, wept, and had remarkable delusions. The pain was of such severity that he had to have morphine. The pulse was very variable, and at one time became extremely rapid, above 160. His face was flushed, not pale.

On Sunday, the 17th, he was better, and on Monday he was all right and attended to his practice. On Tuesday, while performing a minor operation, he had a recurrence of the agonizing pain. He said: "Words can not describe my torture, but I went on and completed the operation."

On Tuesday evening he had another severe seizure, and had to have morphine hypodermically, and took chloral and bromide through the night.

On Wednesday he was in very bad condition, was nervous, emotional, and quite delirious. On Thursday he was annoyed by a cabman, and had an attack in the street, which upset him very much, but which was not, however, followed by delirium.

Altogether, in the past eight days, he has had five or six paroxysms of great intensity. In the attacks his wife says he is very restless, gets quite beside himself with the pain, and demands morphine at once. He has had all sorts of delusions, and has been in a most unnatural mental condition.

Patient was very healthy-looking, evidently very high-strung and nervous, a man who had for years lived far too intensely, and had worked very carelessly and with too much friction.

The physical examination was entirely negative. The pulse was quiet, without increase in tension. The heart sounds were clear, without accentuation of the aortic second. The vasomotor system was extremely labile, and the slightest scratch was followed by an active reaction.

The persistence of pseudo-angina is sometimes very remarkable. In 1888 I was consulted, in Philadelphia, by an old friend, a physician from the Province of Quebec, who had very severe heart disease. While I was visiting him late one evening at the Lafayette Hotel, he asked me to step into the next room and see his wife, a woman sixty years of age, whom I found prostrate on the bed with her hands clasped over her heart, rocking herself from side to side, in an agony of pain. Her hands and feet were cold, the face somewhat flushed,

the pulse small and rapid. I could not get an answer from her, but when I returned to the room the doctor said not to worry (I seemed anxious about her), that she would come all right in a little while. He assured me that for more than thirty years she had been subject to these attacks, particularly when overanxious or worried. She was a very nervous woman, had been hysterical when young, and though at first her husband and other physicians thought the attacks very serious, they passed off so quickly, particularly under the influence of a hot whisky punch, that he had ceased to regard them as in any way dangerous.

*Vasomotor phenomena* are rarely absent in attacks of true angina, but they are even more pronounced in the nervous and hysterical subjects. Nothnagel has described a special type, *angina pectoris vasomotoria*.\* In the four cases (all men) the symptoms consisted of peculiar sensations in the extremities or on one side of the body, with coldness and sometimes lividity of the hands and feet and sweating. With this there were palpitation of the heart, terrible præcordial anxiety or pain, and sometimes feelings of faintness. A striking feature in these cases was the tendency of the attacks to occur in the cold, or on washing the hands in cold water. Nothnagel regarded these vasomotor phenomena as the primary features, and the cardiac embarrassment and distress as secondary to a widespread vaso-constrictor influence throughout the arterial system.

A good deal of discussion has taken place upon the propriety of recognizing this as a special type, and considering the frequency of vasomotor changes in both organic and functional forms it does seem doubtful; and yet the cases are wonderfully well characterized and in the most pronounced degree always, I think, of the functional variety. In a large proportion the vaso-constrictor influences dominate, and there is pallor with coldness. I remember but one instance in which the vaso-dilator phenomena alone were marked.

In 1887 I saw (Case VII), in Toronto, a lady, aged thirty-five years, stout, well nourished, the mother of five or six children, who had been the subject, at intervals, of very puzzling and distressing attacks. Without any special reference to the menstrual period, and following particularly worry or excitement, she would experience a feeling of distress about the heart amounting to actual pain, and the vessels of the face and of the extremities would become congested, and she felt cold and numb. But much more distressing than these were the sensations of great pain in the back of the head and neck. The attacks would last for twenty-four hours or more, and were sometimes very alarming. I could not gather from her that the pains about the heart were ever of a very agonizing character, but they were always severe. I was asked to see her to determine the presence or absence of a heart lesion. Both sounds seemed perfectly clear, and there were no signs of organic disease. I was much impressed with the evident neurotic condition of the patient, and suggested hys-

teria. I saw the patient in an attack, evidently hysterical; she was greatly prostrated, lay with the eyes closed, quite livid in the face, and the hands and feet were purplish in color and cold. She complained of great distress about the heart and agonizing pain in the back of the head and neck. The subsequent history has borne out the view taken of her case. Within a year or so she got perfectly well and has remained so, not having had an attack for nearly eight years.

Much more commonly there is pallor with the coldness. In women the attacks are apt to recur at or before the menstrual period.

Mrs. R. (Case VIII), aged forty years, consulted me in 1890 about attacks of severe pain in the region of the heart, which had recurred at intervals for eight years, since the birth of her last child. They were particularly liable to come on during the menstrual period, or whenever she was subject to any special mental strain or worry. The pains were very severe, immediately under the left breast, and passed up the neck and down the left arm. She did not flush with them, but, on the contrary, got pale and felt very cold, particularly in the hands and feet, which sometimes sweated. The pains were not continuous, but recurred at intervals extending over a period of several days. Diet, she thinks, had no special influence. She slept badly and dreamed a great deal. The patient was a stout, well-nourished woman of good color; the pulse was regular, about 80; the arteries were not sclerotic. There was no heart disease.

In women, as you will have noticed in the reports I have read, the features of coldness of the extremities with numbness and pallor are very common. In men this type may occur in a most marked degree, and the diagnosis may be for some time in doubt.

CASE IX.—A. B., aged forty-two years, seen December 30, 1895, complaining of paroxysmal attacks of terrible intensity, characterized by a feeling of suspended animation, as though the breath had left the body; at the same time the hands and feet get cold, and there is a sensation of stricture about the root of the neck.

The patient, who occupies a prominent position of trust, looks a healthy, vigorous man. His family history is excellent.

As a young man he was very well. He has never had syphilis; is a moderate drinker, and has used tobacco freely. Seven years ago, following a period in which he was very much overworked, he first had the attacks, which recurred for nearly eighteen months. At that time they caused him great alarm, but with the exception of two, they were not very severe. The present attacks date from just two months ago. He has been in his usual health, and knows of no special cause why they should have come on. A majority of the paroxysms have occurred at night, just as he was beginning to doze to sleep. He has had them also on the street, and seven years ago in one he had slight vertigo, and had to sit down on some steps, and he felt as he sat upon them as though they were rising and falling. The attacks may come on while he is sitting at his desk, or while he is reading quietly in his chair. Exercise is very apt to bring them on, and if he runs for a car or hurries upstairs he is apt either to have a severe attack or to experience a chilly feeling and the sensation which he

\* *Deutsches Archiv, f. klin. Medizin*, Bd. iii, 1867.

constantly speaks of as though his breath had all left him.

The sensations which he describes in the attack are very curious. He lays special stress on the feeling that the respiration had ceased, and it gives him some relief to draw several deep breaths. With this is associated a sense of great stricture about the lower part of the neck, and a terrible sensation about the heart, as though it was his last minute. He feels strangely in the head, and thinks he has a very wild look. The face becomes pale, the hands and feet get cold as ice, and become very clammy with perspiration, and in several attacks he has had a feeling of numbness in the legs from the knees down. He lays very great stress upon the sensation of coldness in the arms and legs, and says that on one occasion he took a warm bath, and even though the water was quite hot he still had a feeling of great coldness and numbness in his legs. In one attack the face and neck became very red and congested, and the nose bled profusely. There is invariably palpitation of the heart, and he has been told by his doctor that the pulse at the wrist becomes scarcely perceptible. In a paroxysm, seven years ago, he thinks he lost consciousness for a moment. He staggered and fell. In one attack at this time he had vertigo. As the paroxysm passes off he belches a great deal of wind. In several spells there has been a good deal of itching of the skin, and in one or two a marked twitching of the muscles. The duration of the entire paroxysm varies from two or three to ten or fifteen minutes. He finds that a strong drink of whisky will sometimes cut short an attack. In the two months since they recurred he has had on an average about four in a week. They have not all been severe. He has been much alarmed about them, and in several of the attacks both he and his wife have been greatly terrified.

Patient was a tall, well-grown, healthy-looking man. There was no arcus senilis; the pupils reacted readily to light. The pulse was soft and full, regular, tension low. The apex beat was just within the nipple line, not forcible; slight throbbing in the vessels of the neck. The percussion note was everywhere clear; there was no increase in the area of heart dullness. The heart sounds were clear; the aortic second was not accentuated; the breath sounds were equal on both sides; there was no dullness in either interscapular region, and no bruit round the course of the descending aorta (a diagnosis of aneurysm had been made). The cervical glands were not enlarged. The examination of the abdominal organs was negative. The knee-jerks were normal. There was no Romberg's symptom, and the pupil reflexes were active.

*January 1, 1896.*—The patient's wife came to-day to speak about her husband's condition. She says that last summer he had a few slight attacks. She mentions several features of interest, particularly the suddenness of the onset. For example, he will awaken from a perfectly sound sleep in a most alarming paroxysm, and his hands and feet will become cold; the face is usually pale, and the heart will throb most forcibly. Within a minute or two his hands will become as wet as though they had been dipped in water. She remembers two or three attacks in which the face became quite congested and full instead of pale. He is greatly terrified, and always feels that he is going to die. What has reassured her always is the fact that within ten or twelve minutes, sometimes less, he is laughing and talking, quite free from pain. She does not think that

he has been a very nervous man, and he has not had any special worries.

*April 1st, 1896.*—For the past two months this patient has been very much better, and, as he tells me, has almost recovered from his attacks.

*June 1st.*—He has not had an attack for nearly four months.

And lastly, in addition to the purely hysterical and vasomotor forms, there are cases in which the angina appears to be excited reflexly, either from peripheral or visceral irritation. You will find an interesting chapter in Huchard devoted to these reflex pseudo-anginas, and he has collected a number of cases from the literature. There are instances of anginous attacks following a cervico-brachial neuralgia, of either traumatic or spontaneous origin. You remember in the histories of the cases of true angina how insistent many patients were as to the influence of diet. There is also a so-called gastro-intestinal form of pseudo-angina, in which attacks follow indigestion. The following is the only instance in my list in which the visceral irritation appeared to induce the paroxysms, or, to speak more correctly, in which the two conditions were associated:

*CASE XII.*—Miss A., aged twenty-two years, seen April 4, 1893, complaining of severe attacks of pain in the region of the heart.

She belongs to a nervous family, and she has never been very strong. She denies having had hysteria. Several times, as a child, she had slight rheumatism, and three years ago she was laid up with a more acute attack. Several members of her family have also had it. For years she has been subject to dyspepsia, particularly after eating too many sweet things. For a year or more she has had occasional attacks of pain in the chest, coming on particularly when she has indigestion. The pains are neuralgic in character, chiefly about the lower part of the chest, yet sometimes, to use her own expression, "they fly all over her." Lately she has been much alarmed by the occurrence of two attacks of great severity, the first about two months ago and the second a month ago. There was agonizing pain in the region of the heart with shortness of breath. Both were severe enough to require hypodermic injections of morphine. The pain, so far as she could localize it, was in the left side, in the region of the heart, not in the abdomen. On both occasions, though the severity of the pain was only, as she said, *for an hour or so*, yet for two or three days after she had more or less pain and distress. On both occasions she had dyspepsia, but she had not been specially nervous or run down. She does not know whether she got pale during the attacks, but she sweated after them. She takes a great deal of exercise, but has never had an attack brought on by exertion.

She looked a nervous girl and flushed easily. The examination was negative, with the exception of slight dilatation of the stomach.

*The Buffalo Academy of Medicine.*—At the last meeting of the Section in Obstetrics and Gynecology, on Tuesday, the 24th ult., the special order for the evening was the subject of Post-partum Hemorrhage, the aetiology, pathology, and diagnosis being discussed by Dr. P. W. Van Peyna and the treatment by Dr. R. L. Banta.

## Original Communications.

A CASE OF  
UNUSUAL LARYNGEAL GROWTH.\*

By J. W. GLEITSMANN, M. D.

ALTHOUGH the history of the patient is incomplete, and unforeseen circumstances prevented the treatment from being carried out to a satisfactory issue, the case is briefly related here on account of the peculiar aspect and nature of the growth which had developed in the larynx.

The patient was shown once this winter in the Laryngological Section of the New York Academy of Medicine, and examined by a large number of its members; but none—at least to my knowledge—ventured to make a positive diagnosis, as the appearance of the growth was so very different from anything which is usually seen in the larynx. Soon afterward, on February 7, 1896, I was agreeably surprised when I saw the patient enter my class room in the German Dispensary—probably because I had previously treated his father-in-law successfully—and I concluded at once to use all possible means to determine the nature of the growth and to relieve the patient.

The patient, a Russian Jew, thirty-three years of age, of small stature but normal build, living in the suburbs of Brooklyn, gave no history of previous disease. Hoarseness set in about a year ago, but otherwise he offered no complaint. He had not lost flesh, had no pain in his throat, no cough, no dyspnoea, and attended regularly to his business—viz., soliciting work on the street in the downtown district as watchmaker. Considering his position in life, he seemed to be of rather bright intellect and quick perception; he was very appreciative of any little attention shown to him, and was a very obedient patient. His hoarseness was permanent, although not of very aggravated character; and the state of his voice remained the same during the whole time of observation and treatment.

The outer inspection gave negative results. The larynx and its surroundings felt normal to the touch; no enlarged cervical glands could be detected. The pharynx appeared healthy, and the larynx presented the following features: The epiglottitis standing almost erect, which position greatly facilitated later operative procedures, a large, almost snow-white mass could at once be seen when the mirror was placed in proper position. At the demonstration at the New York Academy it could not be definitely ascertained if what was seen was a tumor or ulcerated tissue with deposit of secretion on its surface, as no probe was introduced. Exploration with the sound, made now, at once proved the mass to be a tumor without any secreting surface, extending horizontally the entire diameter of the larynx from the anterior commissure to the arytenoid cartilage. It was confined to the right side, and appeared to be located between the false and true cord, although of the latter nothing could be seen at this period. If I may be allowed

to use an unscientific expression, the impression I had at the first and at subsequent examinations was that the growth looked very much like a bunch of cotton which had been inserted all along the ventricle of Morgagni. The whiteness of the growth was homogeneous in its entire length, its surface very little corrugated, its free border slightly irregular.

The other parts of the larynx presented no anomalies worth mentioning. The right ventricular band seemed a little narrower and slightly hyperæmic. The right arytenoid cartilage was not enlarged. The movement of the right side of the larynx, upon which point special attention was bestowed, was very little, if any, impaired, and adduction of the cords seemed to be perfect.

As it was deemed inopportune to treat the patient at the dispensary, he was directed to my office, and about a week later the first attempt of excising a part of the growth was made. It was not intended at the time to remove the whole tumor, but only to obtain a sufficiently large piece for microscopical examination. The operation was done with Landgraf's double curette, devised for excision of the ventricular bands; and, although the tumor was denser than expected, it was not as hard to dissect as we often experience in tuberculous infiltrations. The bleeding was slight, but for an hour the expectoration was tinged with streaks of blood. There was no unpleasant reaction; the after-treatment consisted of paintings with weak solutions of lactic acid, and later of mild astringents and applications of sprays and iodol. Unfortunately, the piece removed proved to be cut not deeply enough to show the real structure of the tumor by the microscope, and on February 27th a second and larger piece was cut out, as deep as the curette would allow me to do. The second operation affected the patient more than the first one, which I attributed partly to the after-effect of cocaine and partly to nervous excitement. The bleeding was not any more than formerly, and, after resting some time, the patient went away alone, promising to return the next day to be demonstrated at a medical meeting.

This visit was the last I saw of the patient at my office, and, when he did not appear within the two following weeks, I concluded to call on him at his house, in which I finally succeeded, after traveling three quarters of an hour in a trolley car and walking twenty minutes more through unpaved streets and on filthy sidewalks.

I found him perfectly rational. He received me very kindly, and stated, as the reason for his absence, that he had felt very weak during the first few days after the operation, and that later one of his children had been

\* Read before the American Laryngological Association at its eighteenth annual congress.

taken sick. He seemed slightly debilitated, but his voice was a little stronger; all his other functions were normal. When examining his larynx, I saw for the first time a part of the true cord on the right side. Although an inspection had been made immediately after the second operation, nothing could be seen of the lower part of the larynx, as the blood oozing from the wound obscured the view. Up to that time I was also not sure if the vocal cord had not become violated by the operation, or if the cord was perhaps not involved in the tumor itself—a point which, of course, was later on decided by the microscopic investigation. At the examination the tumor was seen to have decreased about a quarter its size, which decrease was naturally most visible at its median portion, where excision had taken place. A part of the vocal cord could be seen through the opening, which was slightly hyperæmic, but seemed not to be changed in its contour. The remaining larger portion of the tumor presented the same appearance as before.

The patient promised again to call in a few days, but, after I had waited in vain three weeks, I determined to visit him a second time, as the case was too interesting for me to let it go by default. My reception this time was very different. The patient, surrounded by a large number of friends, received me with a sullen face; told me there was no need of my coming, as he had not sent for me, and when desirous of my services, would call at my office. He spoke in a rambling, incoherent, unintelligible manner, and I learned, after much parleying, from a relative that the loss of his child, followed by the death of his father-in-law, had upset his mind, and that only the day previous he had been forcibly removed from the tracks of the railroad near by, where he was attempting to commit suicide in this manner. He did not allow me to examine his larynx, and without accomplishing anything I was compelled to leave.

As I was convinced after this experience that further attempts would be equally fruitless, I felt obliged, to my great regret, to relinquish the case. Our interest naturally centres in the character of the tumor. Both specimens were examined by Dr. Schwyzer, the pathologist of the German Hospital. Before reading his report concerning the second piece removed, I beg to mention that allusions to whitish-looking tumors of the larynx are very scarce in literature. I have found no statement to this effect in the text-books in my possession. In his treatise on cancer of the larynx, 1889, B. Fraenkel says that it is an erroneous impression that in an early stage cancer of the vocal cords produces hyperæmia or inflammation. On the contrary, the carcinoma often presents a surprisingly white appearance. Further, Semon says, in a lecture on Benign Growths of the Larynx (*Clinical Journal*, February 20, 1895): "Unusual snow-white color or grasslike appearance of tumors points strongly to malignancy."

The report of the microscopist is as follows:

"The tumor may be defined as a papilloma durum laryngis. It is composed of proliferated papillary mucosa, covered by a thickened epithelial layer. The surface layer of epithelial cells presents itself as a horny covering; the underlying epithelial cells show marked proliferation with a splitting up of the nuclei. The submucosa shows a small-celled infiltration in conse-

quence of connective-tissue proliferation. The epithelial layer shows a tendency to invasion of the subepithelial tissues as in carcinoma.

"The glands at the margin of the new growth appear very much changed. The individual tubules or ducts should appear distinctly separate one from another, instead of which, and at certain points, the cylindrical epithelium appears to merge from one duct to another.

"This condition also gives rise to a strong suspicion of malignancy, and justifies the following diagnosis:

"Papilloma durum, probably malignum, and perhaps carcinomatosum."

I have nothing to add to this report, but am inclined to believe that, if either the whole tumor could have been removed, or the excision had been made from a still deeper layer, a malignant character of the tumor would have been more firmly established.

#### SOME OF THE UNUSUAL MANIFESTATIONS OF SO-CALLED "CATARRHAL LARYNGITIS."\*

By CLARENCE C. RICE, M. D.

SUCH a constant relation is nearly always found to exist between congestion of the larynx and catarrhal disturbances of the respiratory tract above, that when we find pathological lesions in the larynx, apparently independent of nasal or pharyngeal disease, we note the exceptional condition at once. Catarrhal laryngitis not dependent upon, or not secondary to, some primary changes in the nose and pharynx is rarely seen. Given a certain amount of nasal obstruction, congestion, and hypertrophy, we always expect to find, as a result, the same kind, but a lesser degree of catarrhal disturbance in the pharynx, and still less in the larynx and trachea. But there are exceptions to this very general rule. We know there are pathological conditions of the pharynx caused by cardiac, gastric, or hepatic diseases, which bear but slight relation to nasal disturbance. Rheumatic and gouty pharyngitis exist, unaccompanied by any nasal disorder. Disease commencing in the faucial tonsils may also produce a general pharyngitis, the nasal passages remaining comparatively healthy. But these conditions are not frequent, and the rule holds good that nasal, pharyngeal, and laryngeal disorders are almost always combined.

There are not many constitutional conditions which select the larynx alone as their point of attack. Laryngeal tuberculosis is nearly always secondary to pulmonary disease. The larynx is but one of the many parts attacked by syphilis. We are not interested here in the various forms of laryngeal paralysis, or of the new growths which are found in the larynx. I wish to call attention to certain local or general congestions of the larynx which are not secondary in any great sense to diseases of the nose or pharynx. While it is possible that we

\* Read before the American Laryngological Association at its eighteenth annual congress.

must look for their causation in the patient's slight predisposition to catarrhal disease of the upper respiratory tract, we shall find, as a much greater cause of the disturbance, some error in the performance of the physiological functions of the muscular apparatus which produces the speaking and singing voice.

These various localized congestions should not be recognized under the name of catarrhal laryngitis, because this term should always be held to mean a general catarrhal disturbance from the nasal passages down.

We are, I say, in the habit of thinking and teaching that a laryngeal catarrh bears the closest sort of relation to nasal disorders. But the exceptions to this rule are found in that class of patients who use their voices in other ways than in ordinary conversation—singers, clergymen, public speakers, and actors. In people of these professions we find laryngeal disorders as indicated by congestion, swelling, and muscular relaxation, but the peculiarity is that the degree of disturbance is out of all proportion to the amount of nasal and pharyngeal trouble.

Before I mention the unusual conditions observed, allow me just a word in regard to the usual forms of laryngeal disturbance. In the most ordinary variety of nasal disorder caused by obstructions arising from the nasal septum, and producing catarrhal congestion and hypersecretion, we rarely find more than congestion of the larynx, confined, for the most part, to the sides and to the epiglottis, the vocal bands not being much affected. This slight congestion affects the speaking voice very little, but the untrained singer would be troubled with hoarseness. But it is a condition which does not prevent those who breathe properly and use their voices correctly from continuing with their work. No surer way of benefiting this simple laryngeal congestion can be found than by putting the nasal passages in good order.

We have a much more difficult task in curing that laryngeal disease which is secondary to atrophic rhinitis and a dry pharynx. We know how common it is to find extreme huskiness or total loss of voice in laryngitis sicca. The congestion is so extreme and the thickening so great, it requires long treatment to restore the tissues to their normal condition.

The laryngeal congestion, therefore, which follows nasal obstruction, and the dry, parched, congested, thickened, laryngeal mucous surface which is secondary to an atrophic rhinitis, represent the two usual types of catarrhal laryngitis seen at all times in all people. The changes in the larynx may proceed to permanent tissue thickening, or even to ulceration.

In regard to the etiology of the rarer forms of catarrhal changes in the larynx, I should say that aside from the predisposition to catarrhal trouble of the upper respiratory tract, which everybody is more or less influenced by, in the cases which I have observed the exciting cause has seemed nearly always to be related to an unusual use of the voice.

First, there is a troublesome type of cases, seen usually in men, and the three or four that I especially remember occurred in bass singers. There was no special nasal disturbance, but there was atrophy of the submucous structures of the middle and lower pharynx, without dryness. There was marked enlargement of the diameters of the middle pharynx, because the tonsils had disappeared and the pharyngeal pillars had shrunk wide apart. The same atrophic changes had taken place in the larynx. The epiglottis was exposed and large; the vocal bands were very long, and always inclined to congestion. There seems to be a special lack of muscular power, manifested by the internal muscles of the larynx, by the thyreo-arytænoids, and the transverse arytenoid muscles. In some of these cases there is evidently atrophy of the muscular tissues; and it is exceedingly difficult to keep people suffering from a general atrophy of the pharynx and larynx in good voice, so much is the proper relation of parts disturbed.

Perhaps there is no more troublesome local laryngeal disorder, whether it causes vocal disability in the singer or a tickling cough in the non-professional, than the permanently enlarged epiglottis, an epiglottis which is too high and too wide, and which is always congested. In many of these cases congestion is confined to the epiglottis alone, and the nose and pharynx are in excellent condition. It is likely that the friction of the epiglottis against the base of the tongue and sides of the pharynx is a source of irritation, and that the increased size of the epiglottis also exposes it to unusual sources of congestion. The disagreeable symptoms attending this condition seem to be entirely due to the abnormal size of the epiglottis, since there are no other laryngeal lesions apparent. The irritability of the epiglottis produces reflex congestion of the entire larynx. Spasmodic closure of the vocal bands is common, and any extraordinary use of the voice causes a tickling and hoarseness which render singing and public speaking impossible unless the voice is very carefully produced. I do not remember to have seen this condition of enlargement of the epiglottis most frequently in singers, so that it does not seem to be produced by an overuse or bad method of singing or talking. Congenital factors may be at fault. Once enlarged and exposed, congestion easily takes place, and constant tissue-thickening goes on. I have seen irritative congestion of the epiglottis remaining in an obstinate way when the nose and pharynx were as nearly normal as possible. Enlargement of the lingual tonsil and disordered relation between it and the epiglottis must, of course, not be forgotten as a cause capable of producing enlargement of the epiglottis.

I only wish to mention, as we pass, the enlargement of the ventricular bands in the condition known as "choked voice." It is difficult to say whether this enlargement of ligamentous structure represents Nature's efforts to supply vibrating tissue in place of disabled true cords, or whether the enlargement of the "false

cords" has been entirely produced by faulty muscular action, such as forcing the sides of the thyroid cartilages together by a too forcible adduction of the bands. In the cases observed, the vocal bands always show a great lack of tension and sustaining power. When a sound is produced the bands come together, but immediately fall apart, as if from sheer muscular weakness, and their place is supplied by the approximation of the ventricular bands. I have only seen this condition in second-rate singers. Overforcing the voice may be put down as its cause. The prognosis in these cases is bad, because actual hypertrophy of the ventricular bands has oftentimes taken place, and they may be seen as shelves, standing well into the calibre of the glottis. It will require the most careful voice production, with painstaking attention to breathing, to give the true cords proper exercise, and to discontinue the use of the muscles which force the false bands inward. I have seen another condition which may not be similar in causation, but which appears somewhat like the "choked voice." This was in a soprano, who breathes and sings in a wretched manner, but who has a strong, pleasing voice. The entire sides of the larynx above the vocal bands stood inward so far that they almost obliterated the width of the true cords. In phonation, the width of the cords seen was hardly more than a line. This patient gets out of voice constantly with every attempt at prolonged singing. The tremendous overuse of the laryngeal muscles not only squeezes inward the sides of the larynx, but keeps the bands congested.

I have seen another interesting condition in two patients, both singers, one of whom is a tenor of a good deal of reputation, who sings all the time, and who is always in good voice. This disturbance might be termed a "congenital vascularity" of the vocal bands. I use the word "congenital" because I have known one of these patients for fifteen years, and both of his vocal bands were just as red when I first saw him as they are now. The congestion in his case does not in any way interfere with the production of tone. This patient had at first a moderate amount of nasal obstruction which was long ago attended to, and also pharyngeal catarrh. I do not think I have ever seen any variation in the color of his vocal bands. He himself does not know but that his cords are white, as I have thought it would discourage him if he knew that his vocal apparatus was different from that of other singers. It is possible, of course, that the enlargement of the blood-vessels of his vocal cords took place before I knew him, as the result of catarrhal changes, but I should rather be inclined to believe that the vascularity, if not congenital, appeared during the first years of his attempting to use his voice in singing. He is a very faithful German, an earnest worker, and he went through a good many mental and muscular struggles in the first years of his professional work. I have seen his larynx recently, and observed that the remaining portions of it were free from congestion. I wonder

if any member of this association treated him during this winter. He caught cold on his trip, and somebody treated his larynx, endeavoring, I believe, to remove the congestion of the vocal bands. The second case of this kind was in a soprano, not specially accomplished vocally. I have seen her from time to time for ten years, and the vocal bands have always been congested. She has very little general catarrh, and her voice, what there is of it, always remains the same. In these cases congestion seems to be the only pathological change, as we could not expect good voice if tissue-thickening or muscular weakness were present. We would not suppose it possible that either of these people could sing at all if they did not use their voices in the most perfect physiological manner. In these cases no blood-vessels can be detected, but the bands are uniformly and solidly red.

Of course the ability to produce a good singing voice under these conditions is not so remarkable as to be able to sing in a church choir acceptably with a paralyzed left vocal cord. I have seen such a case in a contralto.

Another interesting but rather slight disturbance in the larynx I have seen, perhaps always in persons using their voices in singing or public speaking, is a localized congestion of some part of the larynx, not catarrhal, reflected downward from above, but congested mucous and underlying muscular tissue, evidently caused by the overuse of some particular group of muscles. I have observed this congestion most frequently involving the arytenoid cartilages, the remainder of the larynx being normal. This condition of the arytenoids does not resemble the bluish, oedematous appearance seen in tuberculosis, but is a healthy reddish congestion, evidently caused by overaction of the transverse arytenoides muscles which force together too strongly one cartilage against the other. I have seen catarrhal inflammations involving only the arytenoid cartilages, which was an extension of a similar process from the posterior wall of the lower pharynx, in cases of pharyngitis sicca. But the difference in the two conditions was plainly observable; in one case the mucous surfaces were dry, in the other moist; in one the lower pharynx was affected, in the other normal. It is interesting to note how little benefit can be obtained from astringent sprays in removing the congestion of the arytenoids so long as the patient is singing, and how quickly it disappears when the patient is not using the voice, or has been taught to avoid the production of any impulse in the larynx in making tone.

The condition known as "chorditis tuberosa," or "singer's nodes," is also a local affection of the vocal bands, not necessarily secondary to any general catarrh, always produced by an overuse of the voice. I have seen this condition produced by a three-days' use of the voice. On Monday, for example, the vocal bands and the entire larynx were perfectly normal, and on Thursday the cords were slightly injected, and the pearly nodules had commenced to make their appearance. This was, however,

in a patient who had had the same difficulty before. She was so well acquainted with the condition, and knew how to avoid it so well, that, although obliged to sing every evening, she used her voice so carefully that without any special local treatment this epithelial thickening was almost entirely gone in two days. These nodular enlargements, so soon as the voice is produced without muscular contraction about the larynx, show a tendency to be drawn upward from the free edges of the cords to the upper surfaces. So much has been read before this association in regard to this condition that we need not speak of it longer, but I am perfectly convinced that it is a condition peculiar to singers, and that local applications are useless so long as the voice is being badly used; but that it disappears rapidly by proper diaphragmatic breathing, and by placing the expiratory impulse necessary to tone production in the forward part of the face and mouth, or well up behind the nose and away from the larynx.

I need not speak in this paper of the rather indefinite condition of the vocal apparatus known as "voice fatigue," characterized by the disability of some one or more of the intrinsic muscles. These cases are common enough. Occasionally we see a patient whose muscular action has become so disordered that apparently an abnormal compensatory muscular action is attempted by the larynx to supply the loss of the feeble muscles. Such patients have a constant hoarseness in their speaking voice, but are able to produce certain low notes in the scale fairly well. The larynx is examined to ascertain the cause of the hoarseness in speaking, and no lesion is discovered, but, when phonation is attempted in any of the vowels, the epiglottis and larynx, instead of being raised, dip downward, and the whole larynx is pulled backward. The antero-posterior diameter of the glottic cavity is shortened, and consequently vocal tension is impossible and the tone is husky. Whether this is a misapplied attempt toward compensatory action for fatigued muscles it is difficult to say.

There may be other peculiar localized disturbances of the larynx which have not been mentioned. I recall no others at present. In saying that most of these are peculiar to singers and speakers, we define their etiology—overuse of the voice, and usually an improper use of it.

Some of the pathological conditions described here are in no sense manifestations of "catarrhal laryngitis," for this term should only be used to designate those inflammations of the laryngeal mucous membrane which can be easily seen to be secondary to and dependent upon similar changes which have taken place in the nose and pharynx.

The facts which I have endeavored to state in this short paper are these:

First, that there are two ordinary types of catarrhal laryngitis, the one following and dependent upon nasal obstruction, or the condition known as "hypertrophic

rhinitis," and the other a laryngitis sicca, which is an extension downward of an atrophic rhinitis and a dry pharyngitis; and that in these two processes the same pathological condition exists, from the commencement of the nose to the bronchial tubes.

Second, that we occasionally see laryngeal disturbances which from their appearance might belong to one of these two ordinary types, but the significant point is that they are present when the nose and pharynx are in excellent condition; or, still again, that the laryngeal disorder, although in kind like that of the nose, is in degree much greater, which is the reverse of the usual condition.

Third, that there are several disturbances of the larynx, commonly classified under the general term of "catarrhal laryngitis," which seem to bear little or no relation to a previously existing nasal or pharyngeal disease, and, as they are observed commonly in singers or public speakers, they are undoubtedly caused by an overuse of the voice and an improper method of breathing and tone production, since they are greatly improved by proper instruction in breathing and singing.

I wish to emphasize the fact that these laryngeal disturbances can not be much benefited by local medication to the larynx so long as the vocal apparatus is improperly used.

Fourth, I have mentioned the following varieties of unusual laryngeal disturbance:

(a) A general tissue atrophy of the soft parts of the pharynx and larynx, which produces a disordered relation and a general muscular weakness of the larynx.

(b) The permanently enlarged and usually congested epiglottis, the larynx, as a whole, being nearly normal.

(c) The "choked voice," caused by actual enlargement of the ventricular bands (the "false vocal cords").

(d) A permanent and perhaps congenital vascularity of the vocal bands.

(e) A localized congestion of some portion of the larynx, probably indicating an overuse of some one of the muscular groups—the transverse arytenoids being the most commonly affected.

(f) The condition known as "singer's nodes," produced by an incorrect method of using the voice, and cured by breathing and singing in a true physiological manner. And.

(g) We see in singers the many appearances of muscular fatigue which are associated with hoarseness and loss of voice; and frequently we observe strange and strenuous efforts on the part of the larynx to supply extraordinary compensatory muscular action for the loss of the disabled muscles.

Fifth, these various laryngeal disorders should be recognized by proper names, and their etiology appreciated, and they should not be confused with the ordinary phenomena of a simple catarrhal laryngitis. And.

Sixth, little dependence can be placed upon local medication of the larynx in these difficulties, unless par-

ticular attention is being paid to instruction in proper methods of breathing and voice production.

## WHY WE SHOULD OPERATE EARLY IN APPENDICITIS.

By JAMES C. KENNEDY, M.D.,

VISITING SURGEON TO ST. MARY'S AND ST. CATHERINE'S HOSPITALS, BROOKLYN.

WITH many physicians at the present day observations and clinical history seem to argue *pro* and *con* as to when a patient should be submitted to operation, thereby proving their inability to solve the problem.

With a limited experience of cases treated on the expectant plan, and a large experience in operative cases, both in hospital and private practice, I have encountered many varieties of the disease, both in its symptoms and pathology; among others, that rarer pathological condition which is frequently fatal even when combated by the most skillful surgery. I have reference to a diseased appendix, filled with pus, with no plastic adhesions thrown about it whereby the general peritoneal cavity would be protected.

In the early operative history of this disease, as did many of my professional brothers, I struggled amid the troubled billows of distrust, anxiety, and doubt, but I felt that a closer observation of my own cases, as well as a study of the cases of other men, would eventually bring me to a guiding principle which would direct me in the treatment of cases coming under my care in the future. As a result of these labors I find myself clinging to the teachings of the more radical surgeons, like McBurney, Morris, and others. Hence the following rule: With an empty intestinal tract, localized pain in the right iliac fossa at the McBurney point, the symptoms persisting and increasing for twelve hours, the diagnosis confirmed by exclusion—operate. In doubtful cases—symptoms lasting and increasing longer than twelve or sixteen hours—explore, inspect, remove diseased appendix if found. Men who have experience in operative work in this disease will here call to mind exceptions to this rule, such as extreme obesity, complications of other disease, as valvular disease of the heart, nephritis (acute and chronic).

It may be of some interest to those who would hesitate to have their patients operated on early that I should relate a few cases which I have treated by both methods—surgically and by the expectant plan. Neither in St. Catherine's nor St. Mary's Hospital have any cases, to my knowledge, been treated on the expectant plan, for the reason that all were decidedly operative; but in private practice I have sometimes (in the past) of necessity and sometimes voluntarily treated cases on a strictly expectant or medical plan, some successfully (for the present, at least) and some with the most disastrous effect.

While the patients did not all recover in the opera-

tive cases, still I, as well as every one present at the operation, thought that the best chance had been given.

**CASE I. Expectant Plan.**—Thomas C., aged twenty-two years, native of this country, theological student.

June 11, 1892.—Complained of pain in the abdomen; bowels constipated. On examination, I found pain diffused over the abdomen, more in left inguinal region; no pain in right iliac fossa over McBurney's point. Temperature, 100°; pulse good. Diagnosis somewhat difficult, but obscure appendicitis kept in mind. Gave castor oil with laudanum, with instruction if the oil did not move the bowels to give a solution of citrate of magnesia.

12th.—No evacuation of the bowels. Magnesia had not been given through mistake; still had slight pain.

13th.—Bowels moved; temperature, 99°; pains very much diminished.

14th.—Felt good, wanted to go down stairs; temperature, 100°; pulse, 94; had not slept much. He was warned to keep as quiet as possible, and under no circumstance to leave his bed.

16th.—After a somewhat restless night he left his bed and began to pace the floor as a sentinel would his beat, when suddenly he felt a pain as if some one had driven a knife into his right inguinal region. His piercing shrieks brought his friends to his side, who found him leaning against the wall with both hands firmly pressed against the McBurney point. He was carefully removed to his couch, when his ghastly countenance told that something was very wrong. I was hastily summoned and arrived at 5 A. M., and found him suffering from severe shock. Temperature, 96°; pulse, 148; skin cold and clammy; with great abdominal pain, severest in right inguinal region; mind clear; pinched and haggard countenance. Hypodermics of digitalis, atropine, and brandy were given, with warmth to the extremities.

Noon, same date, pulse 132; temperature, 95°; condition generally unchanged.

Two P. M., same date, condition about the same; 10 P. M., condition unchanged, except that temperature had gone down to 93°; pulse had gone up to 148.

16th.—At 5.30 A. M patient died.

This case is instructive inasmuch as it shows not only the difficulty sometimes experienced in diagnosis, but the great danger of the expectant plan of treatment.

**CASE II. Treated on the Expectant Plan.**—Looking over my notes, I find recorded there the following case: N. G., aged nineteen years, native of this country; previous health good.

July 16, 1894, 1 P. M.—Took severe pain on right side of abdomen low down; 6 P. M., same date, I saw him. Pain right over the region of the appendix and nowhere else; temperature, 100.4°; pulse, 96. Diagnosis: acute appendicitis; ordered light flaxseed poultice, with salines every two hours until bowels moved.

17th.—Evacuation from bowels; pain almost gone. Temperature, 99.2°; pulse, good.

18th.—No pain, but some tenderness on deep pressure over the appendix. Temperature, normal; pulse, normal. Advised that patient keep quiet until this tenderness on deep pressure entirely disappeared; should it return, however, I should be informed.

In a few days he reported entire absence of tenderness on the deepest pressure. In this case I did not pro-

pose operation for the reason that all the symptoms rapidly subsided within the twelve hours instead of either increasing or remaining stationary. This patient has been under observation since July, 1894, and I am positive he has had no recurrent attack.

No sane surgeon would operate in such a case as this if we had any means of vouching for the result which took place. But for the one case that terminates in this way, fifty will recur, and some of the recurrences may prove fatal. That this was not a case of mistaken diagnosis I have but to say that I used here, as in Case I, the skill in diagnosis at my disposal, the same which I used in a very large number of cases where diseased appendices were removed.

To tabulate or give in detail the many cases of appendicitis that have occurred in my service in two hospitals and in private practice would be a repetition of what has been written many times before; nevertheless, they would speak loudly for early operation.

**CASE III. Late Operation.**—John H. F., aged twenty-eight years, German; sent into my service at St. Mary's Hospital on January 31, 1896, with the following history and symptoms: sick for one week; on admission, temperature subnormal; pulse small, thready, and frequent; abdomen distended; abdominal muscles rigid and cedematous. Diagnosis: appendicitis with perforation. Oxygen and ether were administered as an anæsthetic; after a cautious preparation a rapid opening was made into the peritoneal cavity at the McBurney point, which was found filled with foul-smelling pus; a portion of a sloughed appendix, with a large concretion, found in the right iliac fossa; patient's condition bad; the abdominal cavity was flushed with warm Thiersch's solution. Perfect drainage was established, and the patient stimulated by every possible means. Notwithstanding all, he succumbed six hours later from sepsis.

Cases of this kind swell the mortality list in hospitals, and perhaps I voice the sentiment of hospital surgeons when I say that physicians do the operation a great injustice by sending patients to hospitals for operation in a moribund condition.

The surgeon of to-day must not only make a strong plea for early operation in appendicitis, but it is a moral obligation devolving upon him to use his influence in the consulting room to urge physicians to contrast with their patients the comparative safety of early removal of the appendix with the dangers of delay.

**CASE IV.**—Mr. F. H., East New York, German, aged twenty-seven years. Diagnosis of appendicitis made immediately by his attending physician, Dr. Myer; sent into my service at St. Catherine's Hospital June 24, 1896, and operated on at once; an incision an inch in length was made through the integument and aponeurosis of the external oblique. The muscles of the internal oblique and transversalis were separated in the direction of their fibres (McBurney). Passing through the transversalis fascia and peritoneum, an inflamed appendix, five inches in length, was at once encountered lying along the inner side border of the cæcum. The mesocæcum was necessarily long. The left index finger, the one usually used for purposes of exploration, was gently

passed over the appendix and upon its mesocæcum low down on its attachment.

On the lower and opposite side to the index finger I passed the flat bone handle of a blunt hook, and by pressing these extremities together I procured a firm hold. Then, with a gentle rotary movement, the appendix and its attachments with the cæcum were drawn through the small opening. The meso-appendix was tied off with catgut, the appendix itself removed, its base inverted and pushed into the cæcum. The serous coverings of cæcum were stitched over it by means of Lembert's suture. The peritonæum and transversalis fascia were brought together with a continuous fine catgut suture. The separated muscular fibres of the internal oblique and transversalis were allowed to fall together, while the aponeurosis of the external oblique, together with the integument, was closed by means of a cross suture of silkworm gut. The patient had no bad symptoms whatever. The silkworm sutures were removed on the sixth day, union complete. He left his bed on the eighth day and the hospital on the tenth day, resuming his ordinary duties.

**CASE V.**—Miss K. O., aged seventeen, native; residence, Evergreen, Long Island; acute appendicitis.

**June 22, 1896.**—Twenty hours from the first symptom was sent into my service at St. Catherine's Hospital and operated upon immediately.

The method used in Case IV was followed, except that the incision was three quarters of an inch. An inflamed appendix with necrosed mucous lining and an incipient slough about its centre was removed.

Left her bed on the eighth day and the hospital on the tenth day, perfectly well.

**CASE VI.**—Miss H. S., aged twenty-five years, native; sent into my service at St. Catherine's Hospital, June 23d, by Dr. Gerri, soon after the diagnosis was made. Immediate operation; same method as in Cases IV and V; patient up in eight days; left the hospital on the tenth day.

The cases recorded here are but a few of the many that might be mentioned. It is left to the reader to draw his own conclusions as to whether they argue for early operation or not.

In conclusion, I would state that I look upon appendicitis as a septic disease from the start, and I believe that the removal of the appendix as soon as the diagnosis is made will place the patient where no harm can befall him or her.

If we wait, within the abdomen is fostered one of the most dangerous and destructive diseases that mark the surgical calendar.

I will raise but one point in the ætiology of the disease, and this has been forced upon me by observation in my own cases as well as the cases of others—namely, many cases of appendicitis have followed rapidly upon attacks of acute intestinal catarrh. It is true that sometimes in fatal cases of acute diarrhoea no lesion has been found, but it is remarked by the best authorities that the hyperæmic membrane pales after death, as does the skin in scarlatina and erysipelas. The presence or absence, therefore, of hyperæmia is no proof of the existence or non-existence of inflammation.

There is nearly always, however, more or less tur-

gescence, visible to the naked eye, present in the mucous and submucous tissues which have been the seat of catarrh, and this is nearly always found in the lower part of the ileum and the cæcum, the sigmoid flexure, as well as in other parts of the colon. This condition of hyperæmia is soon followed by acute œdema and increase in the cell elements, softening, and, in fine, all the requirements of a genuine inflammation. That this condition of the mucous lining of the ileum and cæcum, produced by an acute intestinal catarrh, should find its way to the mucous membrane of the appendix, thereby setting up an acute appendicitis, is not an unreasonable idea.

Thoroughness of technics, in surgical operations, now in vogue, prompted by bacteriological research, bordering upon perfection, renders early operation in appendicitis almost without danger. I am in accord with those who contend that appendicitis is a surgical disease and should be treated as such.

762 WILLOUGHBY AVENUE.

### THE OPERATION FOR DEVIATION OF THE NASAL SÆPTUM.\*

By ARTHUR W. WATSON, M. D.,  
PHILADELPHIA.

It is said that the non-success of the treatment of a disease may be judged by the number and variety of the drugs recommended. If the same applies to surgery, surely, the number of methods that have been devised for correcting deviation of the nasal sæptum may be taken as an indication of the unsatisfactory nature of the results.

That the opinion of many writers agrees with this proposition is evident if we consult the latest works on the subject. Thus McBride says: "My experience has been that deviations of the sæptum are not a very satisfactory class of cases to treat"; Bosworth, after enumerating the various operations for straightening the sæptum, advises sawing off the projecting spurs and angles; Jarvis recommends removal of pieces of the deflected sæptum by the *écraseur*; Lennox Browne contents himself with producing perforations by the galvanocautery, and several writers recommend electrolysis (only another method of destroying tissue) in the treatment of deviations of the sæptum. Such methods do not correct the deviations and, it seems to me, are only an acknowledgment of failure.

The symptoms caused by a deviation of the sæptum are not confined to those arising from obstructed respiration. They include interference with drainage, obstruction of the outlets of the accessory sinuses, symptoms due to the abnormal size of the opposite nasal chamber, and that large class of affections caused by contact or pressure known as reflex. The relief of respira-

tion, therefore, is not all that is called for in these cases.

Of those operations that attempt the straightening of the sæptum, the most important are: Adams's, forcible breaking of the sæptum, followed by metal plugs or splints; Steele's, incisions by the stellate punch, followed by plugs; Roberts's multiple incisions by the knife, the fragments retained by pins; Ingals's, excision of a wedge-shaped piece and suture; and Roe's, crushing by special forceps, followed by anti-septic plugs. Allen's operation, in which the base of the sæptum is detached beneath the mucous membrane and the sæptum moved toward the open side and retained by a plug, does not aim at reducing the deviation, but simply equalizing its encroachment on the nasal chambers. By all these methods, with the exception of Ingals's and Allen's, the curved sæptum is forced into a straight line, for which it is obviously too large, and for that reason the results must be but temporary in the majority of cases where the deviation is at all marked.

What, then, are the requirements of an operation for the correction of a deviated sæptum in order that the result may be permanent? This may be considered in two parts: The operation proper, or the method of reducing the deviation, and the means for holding the parts in position until healing has taken place.

Many of the operations devised have been unsuccessful because they lose sight of the fact that a deviated sæptum is larger than a straight one, and make no provision for reducing the amount of tissue. The first step, therefore, is to reduce the sæptum to a size that will fit into a straight line between the points of attachment. This can be accomplished by excising a portion of tissue in the general line of deviation. If the deviation is horizontal, an elliptical piece is removed, the incisions gradually converging at either end. If the line of deviation is vertical, a triangular or wedge-shaped piece is cut out, the apex being upward and extending as high as possible, and the base reaching to near the base of the sæptum, where it may be joined by a horizontal incision. Both forms of deviation are frequently met in the same case and then both incisions are to be made. The excised portion should include the protruding angle. The amount of tissue to be removed can be estimated by the eye. A very important point in this part of the operation, in my estimation, is to avoid cutting the mucous membrane on the side opposite to the incision, a point first noted, I think, by Dr. Ricardo Botey, as the membrane helps to hold the edges in line and thus facilitates union and prevents perforations. The incisions should be made on the convex side of the sæptum.

To bring the bony portion into line the crushing forceps can be used to advantage, and as the fragments slide somewhat on each other it is unnecessary to remove any of this tissue. For this purpose Adams's crushing forceps is generally used, but I should think, although I have not tried it, that Dr. Roe's forceps would do better.

\* Read before the American Laryngological Association at its eighteenth annual congress.

The second part of the operation, the method of retaining the septum, is, I think, very important. I believe one reason for failure in this operation to be that the retaining force is not kept up long enough.

In dealing with the cartilage it is well to remember that it unites by fibrous tissue, and that if the resilient cartilage is allowed too soon to exert its force this tissue will stretch and the deformity be renewed. I have found by experience that from three to four weeks should be allowed for the healing of the cartilage. I have known the supports to be removed within a week and even sooner, sometimes plugs being introduced afterward at night, sometimes frequent finger pressure being resorted to to keep the septum in place, which only stretched the parts and increased the tendency to relapse.

With this point in view it will be seen that hard substances such as ivory, wooden, or metal plugs, and tubes are inappropriate, as by their constant pressure they will produce pain and ulceration. All plugs accumulate secretions which become irritating and offensive, and if removed for cleaning give pain in reintroduction. Splints and clamps have some of the same objections, besides being inefficient. They are also conspicuous, which, as they should be worn for weeks, is important. A pin (first suggested by Dr. J. B. Roberts, but not of the same shape or used in the same way) with a flat ring-

head, the ring covered by a piece of rubber tubing, I have found to be the best support for the cartilaginous septum. The pin is inserted from the concave side of the septum, just back of its anterior edge, and passed diagonally through to the other side, then across the vertical incision, if there is one, and then back into the septum until the head lies on the septum within the nostril. Care should be taken not to produce a deflection in the opposite direction. This method leaves both nostrils free for respiration and cleansing. I have found that if the head of the pin is padded as described, no ulceration takes place, and the pin can be worn for three or four weeks without discomfort.

As the pin supports the cartilaginous part only, the bony septum, when deviated, may require some other support. A piece of iodoform gauze, folded to as many thicknesses as is necessary and not more than a third of an inch wide and three quarters long, placed between the septum and outer wall at the point of deviation, will support the septum and give no inconvenience. The pad can be changed as often as necessary for cleanliness. As the bony portion unites more quickly than the cartilaginous, the pad can be dispensed with in a week or ten days, leaving the pin to do the rest.

In order to do this operation properly the parts must be well illuminated and as free from blood as possible. For this reason cocaine anæsthesia should be used in preference to ether.

In many cases, especially where the deviation is marked and low down, it is impossible to bring the lower fragment into line. The result is that there is nothing to meet the upper fragment and non-union results. To overcome this difficulty I have devised the following modification of the operation:

Instead of cutting out an elliptical piece along the horizontal line, I make an incision, which may be called a beveled incision. The edge of the knife is directed upward and toward the opposite side, and carried through the cartilage, but not the mucous membrane of the opposite side. The incision is made just on the crest of the deviation. Any vertical deviation is cut out as before described. The upper portion is then pressed over toward the other side, where it hooks itself on to the lower, and is thus held in place. This also uses up the redundant tissue. The projecting base can then (or after healing) be removed by the saw. This diagram will

Diagram showing, 1. Deviated septum with line of incision. 2. Septum re-placed, with spur standing. 3. Projecting spur removed.

perhaps convey a clearer idea of the method than my description.

I have used this method in a number of cases, and on subsequent examination, months after, have found the parts in good position, the only proof of success in these cases.

No. 126 SOUTH EIGHTEENTH STREET.

## ANIMAL THERAPY.

By THOMAS OSMOND SUMMERS, M. A., M. D.,

F. S. & C. LONDON, ETC.,  
PROFESSOR OF ANATOMY AND HISTOLOGY,  
COLLEGE OF PHYSICIANS AND SURGEONS, ST. LOUIS.

If there is any one thing which contradistinguishes this age of therapy, it is the lessening of therapeutic agents by physiological methods of therapy, which have been shown to possess the power of

1. Antagonizing specific pathogenic germs.
2. Distributing to their ultimate destination nutritive material.

3. Stimulating the physiological functions by normal physiological influence.

Among the higher class of scientists the old principle of artificial antagonism to disease by means of vegetable and mineral drugs is rapidly passing away, although there are yet a few who are so committed to the philosophy of chemical therapy that they are loath to

yield the fact now established that the animal organism contains within itself the physiological principles of resistance to all forms of disease, and if it were possible to extract them in their normal environment, with their relations and effects unchanged, we should then come very near to the solution of that problem of therapy which has been, with its multiplicity of unknown quantities, the acknowledged enemy of medical science—the Cassandra of modern medicine.

The fact, now universally acknowledged by scientists without exception, and even known and recognized by the intelligent laity, that the millions of pathogenic germs entering into the organism at every breath would go on to the immediate destruction of the tissues of the body, is of itself an argument *a priori* in favor of the existence in the organism of cellular agents of resistance to pathogenic germs. The first actual demonstration of this fact was given to the world in the discovery of the cellular principle of nuclein, which physiologists found to be the result of the action of the blastema of the multinuclear leucocytes or white blood-corpuscles upon the proteids delivered to the blood from the digestive tract after all digestive action has been exhausted upon them. Now, then, we have the primal physiological act in the widely extended functions of nutrition and assimilation. The great principle of molecular affinity prevails in physiology with as much certainty, and the laws as invariable and unalterable, as the atomic affinity of chemistry. Physiologists, therefore, reasoning upon this principle, were not long in coming to the conclusion that the organism itself possessed its own powers of resistance to pathogenic germs, as well as its property of converting into tissue the prepared agents of nutrition.

Metchnikoff's theory of phagocytosis startled the profession into the conception of a higher therapy. The swallowing or incorporating of particles by certain of the body cells called phagocytes, is the rationale of this philosophy, which practical experience has proved true.

Having once established this fact, it was but a short step to the conclusion that the organism itself contained its own principles of resistance to the elements of pathology. To this end all scientific therapists began to direct their efforts. As a result, they found nuclein to be the agent of assimilation, as well as resistance to the advances of pathology. This being established, the next practical and most important question was presented—"Is it possible to extract this principle for therapeutic use?" In answer to this Dr. Vaughan, of Ann Arbor, brought to bear his skillful chemical methods, and from the yeast extracted what he states to be, and what other scientists have affirmed, the principle of nuclein itself.

Then came Dr. Aulde with his preparation of nuclein extracted by chemical methods from animal organisms.

When, however, it came to be considered that nuclein could not exist without its environment, that it

could not be extracted or preserved in its cellular activity without its normal envelope of tissue, protonuclein was produced, with the idea of retaining the environment necessary to the preservation of its functional activity, and without any effort to extract the nucleinic principle alone. By this method it was possible to reach pathological conditions unapproachable before. Protonuclein received its name from Professor Huxley's principle of protoplasm, which it represents both in structure and function. It will therefore be readily seen that the establishment of the fact that the principles of nutrition in the organism may be reinforced by those gathered from other animals in itself means a revolution of therapy. Once recognized as a principle of nutrition, assimilation, and antagonism to germs, it has no limit to its therapeutic application.

*Composition.*—It is almost impossible to obtain an exact formula for nuclein, which was first discovered by Miescher in the pus corpuscles and the yolk of the egg. Physiological chemists, however, have generally agreed upon the following:  $C_{20}H_{40}N_9P_3O_{22}$ . A fresh preparation is a colorless, amorphous body, soluble to a slight extent in water, no attempt being made to separate it from its immediate physiological surroundings. It has also been discovered by Professor Chittenden, Dr. Vissman, and others of the Polyclinic School in New York and the laboratories of St. Louis, that protonuclein contains a very appreciable portion of iodine in its environment as extracted. This, of course, would tend greatly to the increase of the absorbent and assimilative functions of protonuclein, bringing it very close to all of the ultimate constructive cells of the body, which is the normal therapeutic action of iodine.

This product, therefore, not only contains the nuclein, but also the nuclein-charged multinuclear leucocytes, which are the active agents of nutrition and assimilation, the vital units of the organism, and the normal resistants to toxic agents introduced into the body. In this way, the activity of the principle is preserved and made applicable to every condition of structure. The large proportion of phosphorus would of itself suggest its general restorative powers, which have been so signally demonstrated in its practical therapeutic application. It is, however, to the cellular activity of protonuclein that its therapeutic power is mainly due, and this contradistinguishes it from all nuclein preparations so called, which have been separated from their normal physiological environment, and can only be useful to the extent of furnishing nutrition to wasting parts provided their activity is preserved, which is scarcely possible without the normal environment, having no effect upon neoplasms or cachexias, which protonuclein attacks with vigor and success. All preparations of nuclein, if they are nuclein, must have the same formula, but it must be thoroughly impressed upon the mind of the medical practitioner that a chemical agent in isolation is not a physiological or pathological agent

in therapy. In many, indeed in most cases, the environment is just as important as the agent, and so far as nuclein is concerned it is all-important to bring into play all of the organic surroundings which render its principles of therapy active in the body. Without these it remains inert. It is just here that protonuclein as a therapeutic agent shows its power over other preparations which claim to possess the nuclein principle of therapy. No effort has been made to extract nuclein in an isolated chemical form, but, on the contrary, every effort has been made to preserve its normal physiological relations, so that it is in a state of immediate activity and assimilability, entering at once into the physiological process of the organism, unaltered in structure, unchanged in functional activity. The other forms of pure nuclein have to undergo a physiological training before they act therapeutically; in other words, they have to gather about them the very environment which is originally taken from the organism in the form of protonuclein. This explains the greater power of protonuclein, for the organism has nothing to do with preparing it for therapeutic action—it commences its normal function at once under normal physiological laws.

There are but few cautions to be observed in its use, being as it is a purely physiological agent, the excess of which in the organism would be quickly eliminated by the *prima viæ* if not utilized therapeutically. There is one exception to this law, however, which should be carefully noted. I refer to its use in carcinomata and sarcomata. As Virchow has shown, the development of a sarcomatous and carcinomatous tumor when first expressed in a part takes on the livery of the structure in which it is imbedded, so that until the whole organism has been infiltrated the physiological power is in excess of the pathological; but when this infiltration takes place all of the corpuscular elements of the body become pathologized as it were, growing even in nutritive channels under the pathological direction given to them. Now, in the first instance, protonuclein, it is evident, would stimulate the physiological action and thus resist the onslaught of the disease. In the latter case, however, the stimulus of growth imparted to the organism by protonuclein would in all likelihood increase the rapidity of pathological expression. In sarcomata the danger line is easily determined by the microscope, for the presence of giant cells in the blood would contraindicate the use of protonuclein. In carcinomata, however, the determination must be made upon general principles. The cachectic look of a patient, the marasmus or wasting, go to indicate the condition of contraindication to the use of protonuclein. In Bright's disease, it is often the case that the administration of protonuclein will temporarily increase the number of casts in the urine, but it must be remembered that Bright's disease is not in itself the disease, but the result of albuminous deposits in the kidney, resulting in ulceration. A moderate use of protonuclein, however, has in most in-

stances even controlled the ulceration. In no other instances can we conceive of protonuclein as contraindicated. To go into the detail of treatment in the various diseases in which it has been applied would transcend the scope of this paper. It is sufficient for the intelligent physician to know that almost all diseases which affect the organism come under the head of one or two pathological conditions—tissue waste or toxic action—and to these conditions protonuclein distinctively applies, as it is the normal tissue builder of the organism, and by virtue of the phagocytic power of its leucocytes it is the natural physiological resistant to all toxic agents:

*Modes of Administration and Effects.*—1. Protonuclein powder, for internal use, combined with milk sugar.

2. Protonuclein tablets, for internal use, combined with milk sugar.

3. Protonuclein, special powder, for local use, with insufflator and powder duster.

4. Protonuclein solution, for hypodermic use.

5. Protonuclein suppositories, for the uterus, urethra, rectum, nose, and ear.

6. Protonuclein ointment, for dermatological use.

These forms, as will readily be observed, are adapted to special characters of disease.

While the doses generally recommended cover the majority of cases, yet there are many organisms which require larger doses from the torpidity of absorption in their membranous structures. It is therefore best to increase the dose when results appear to be negative. I have yet to find a case that has not responded to its use, and it has been used in over nine hundred cases in hospital and private practice. Usually there is an increase of pulse and temperature for the first five to twenty hours. In cases of anæmia, chlorosis, malaria, and all chronic affections, the patient does not often feel for the first few days the peculiar thrilling effect of protonuclein, but the improvement both in feeling and outward appearance is very distinct and oftentimes rapid. The increase of pulse and temperature for the first twelve to twenty-four hours is due directly to the rapid leucocytosis induced. Of course, this subsides as soon as the leucocytes become distributed through the organism and deliver their nuclein to the remote parts of the body, where it is most particularly needed. On account of this rapid distribution, as would be expected, pulse and temperature subside.

Now with regard to the effects of protonuclein upon the pathogenic conditions of the body, it is clear that the range of its therapeutic action, if we grant the first functional power of tissue-building and of resistance to pathogenic germs, must be almost unlimited. Indeed, it has been tested so far in therapy that the results obtained have been with but few exceptions in perfect accord with the physiological principles upon which it is based. It is very clear from the clinical reports which have come in from every source, from Professor Chitten-

den's and Dr. Vissman's elaborate and thorough investigation of the cellular constituency and relationship of protonuclein, and from Metchnikoff's corroboration of them by experiments of his own, that it is the principle of leucocytosis, so active in protonuclein, which determines its therapeutic power. An agent capable of producing leucocytosis to the extent which all scientific investigators who have experimented with it declare, without exception, must be recognized as a most valuable addition to the *Pharmacopœia*. In the hands of the scientific practitioner, even without previous clinical corroboration, it can not but be an agent of infinite therapeutic application, and as its use becomes more general, and its distinctive effect in various diseases more definite, protonuclein will prove a ready and reliable therapeutic agent or adjuvant in most all pathological conditions.

The stimulant or, to speak more physiologically, the excitant effect of protonuclein really shows that its therapeutic power has been asserted. Such excitation is a positive proof of the fact that its cellular activity is expressed, upon which depends the curative effect. Leucocytosis in any part is generally accompanied by increase of temperature and pulse, and yet this natural result has caused some physicians to discontinue the use of the remedy; but I can state positively and with authority that it is a normal therapeutic effect. Though sometimes absent, such absence is due to other conditions which lower the temperature and pulse. The elevation of temperature and pulse, however, is but temporary. The balance of the organism is soon established, and the circulation settles down to the normal relationship to the conditions of the organism. In many diseases I have found, and my colleagues have corroborated this fact, that protonuclein comes very near to a specific remedial agent.

In typhoid fever, for instance, it does certainly control the pathognomonic symptoms belonging to this disease. Whatever theories may be brought forward to prove that typhoid fever is a self-limited disease, we are brought face to face with the fact that such a control has been obtained by the use of protonuclein. Protonuclein, during the first stages of typhoid fever, will, in every case, even the most asthenic, prevent the ulceration of Peyer's patches. It arrests directly the germinal activity of the disease, sustains the organism by direct physiological means, and throws about all the cell life of the organism a wall of resistance, while at the same time it furnishes the resources of recuperation and repair.

In ulcers I can positively assert, and I am sustained by the experience of those whose daily work is devoted to this class of patients, hundreds of them coming into the hospitals and dispensaries under previous conditions most unfavorable for treatment, that in such cases protonuclein invariably produces granulation in twenty-four hours, and the most inveterate cases have been dis-

charged within two weeks' time from the beginning of treatment. The records of the St. Louis Baptist Hospital, the Missouri Baptist Sanitarium, the City Hospital, the Dispensary of the College of Physicians and Surgeons, and the Missouri Pacific Railway Hospital can furnish positive evidence of the facts here stated.

In acute disorders due to germinal influences, such as coryza, erysipelas, gonorrhœa, and, in fact, all classes of acute specific diseases dependent upon zymosis, its antizymotic effect is immediately shown. At one of our outdoor dispensaries, where perhaps a larger number of patients are treated for these acute and especially eczematous disorders, nothing else is used; and especially in cases of gonorrhœa does the injection of protonuclein exhibit a most wonderful effect, destroying the gonococci within forty-eight hours without resort to other remedies. In phthisis, while of course we can not in this short length of time, since the introduction of protonuclein, state positively that it cures the disease, according to all appearances this fact is well established: it does arrest it, builds up the tissues, and will obliterate every evidence of the disease, destroying the pathological condition upon which it depends.

I append herewith what has been furnished us authoritatively as the principles which go to make up protonuclein, and its mode of manufacture succinctly stated. I do this for the reason that an impression has prevailed in the minds of some of the profession that protonuclein belongs to the class of secret or proprietary remedies, whereas it occupies the same relations to other nuclein preparations that Squibb's ether, chloroform, and other preparations bear to those of the ordinary market.

Protonuclein is prepared from the following glands. Take

- 100 pineal glands and pituitary bodies of the brain,
- 100 salivary glands,
- 100 thyroid glands,
- 100 pancreases,
- 100 inner linings of the stomach,
- 100 Brunner's glands and Lieberkühn's follicles,
- 100 thymus glands,

These are derived from the pig, with the exception of the brain, which is obtained from the ox. The methods and means to secure glands from healthy animals are carefully supervised by expert observers. All of the inert tissues are separated from the glands, after which they are passed through a disintegrating machine, and quickly dried by forcing warm air through them by a specially prepared machine, so rapidly that no change can possibly take place, for the vapor of benzoin is passed upward through the desiccator, enveloping the cellular elements and preserving them intact. They are then exhausted with ether, to remove any fatty matter, and again thoroughly dried by the same process, and the portion of the gland that is richest in nuclein, which consists of a little over one third of it, is then separated

from the whole mass by special machinery. It should be borne in mind that the portion of the gland containing the nuclein is very readily converted into a powder, and consequently is easily separated from the inert matter by sifting.

## JUVENILES WITH GONORRHEA.

By LUCIEN LOFTON, M.D.,

ASSISTANT TO THE CHAIR OF ANATOMY,  
AND ASSISTANT DEMONSTRATOR OF ANATOMY, SOUTHERN MEDICAL COLLEGE,  
ATLANTA, GA.

SEEING an article from the pen of Dr. E. S. Cox, of Galveston, regarding a case of gonorrhœa complicated by a double epididymitis, in a lad twelve years of age, recalls to my mind two cases that came to the venereal clinic of the Southern Medical College in December, 1895. One of the boys was four years of age, while the other one was nearly five. The mothers of these two youngsters, being colored people, were not very much alarmed over the condition of their respective hopefuls, and seemed to take the matter as a huge joke. One of the cases was complicated by a violent cystitis, while the other boy made a rapid recovery under the usual treatment. Just how these little "coons" fell heir to such an unusual legacy could not be ascertained. The mothers were examined, and found free from any gonorrheal taint, while inquiry was made regarding the fathers in this direction, but nothing definite could be learned. It was, however, pretty clearly established that the boys did not contract the disease through other than the regular source. The cases were not bastard gonorrhœa, for a microscopical examination was made of the discharge and Neisser's gonococci were plentiful. I consider these two patients among the youngest ever reported with gonorrhœa. The Georgia "coon" beats the world when it comes to venereal disease.

## Therapeutical Notes.

### The Treatment of Snake-bite by Calcium Chloride.—

The *Indian Lancet* for August 16th publishes the following abstract from the *Semaine médicale*: Phisalix and Bertrand reported the result of experiments with calcium chloride in cases of snake-bite at a recent meeting of the Académie des sciences. Its therapeutic action is not, as Calmette thought, due to the formation of some substance neutralizing the poison, or to its entering the circulation and there destroying the poison as it would in a test-tube, but it depends simply on its local effect; it destroys the poison locally, causes the tissue to slough, and so prevents absorption of the toxic material. Hence it is concluded that the injections of calcium chloride must be made deep at the actual spot where the fangs entered, and that they are useless if made in any other part.

## THE NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M.D.

NEW YORK, SATURDAY, OCTOBER 3, 1896.

## THE JUBILEE OF ANÆSTHESIA.

CELEBRATIONS are good things, provided they are well ordered and come not too close together. To celebrate duly some cardinal anniversary of a great event in medicine can not but act as an added stimulus to further striving after other advances. The echoes of the celebration of the centennial of Jenner's beneficent discovery have not yet died away when we have close at hand that of Morton's no less blessed achievement. It is seldom that one particular day stands out as that on which a great medical event happened; usually it is only a year or perhaps a month that is recognized as the one in which a medical discovery or demonstration of great magnitude occurred, for such an event commonly has to undergo a gradual molding in the mind of the man who is chiefly instrumental in bringing it about. So it was, indeed, with Morton's arrival at conviction and confidence in the matter of surgical anæsthesia, but it was on a precise date, the 16th of October, 1846, that that conviction and that confidence were demonstrated to be well founded. On that day, in the operating-theatre of the old Massachusetts General Hospital, an institution that will always be historic on that very account, young Morton, dentist and medical student, made in the presence of the grave staff of surgeons and an expectant but mistrusting crowd of students an attempt which, had he failed, would have brought unbearable ridicule on him, however little it might have postponed his or some other man's success. Surely, his was no ordinary courage, no half-hearted confidence.

Commenting on the magnitude of Morton's discovery, our excellent contemporary the *Boston Medical and Surgical Journal* says editorially in its issue for September 24th: "The 'cruel' knife has become an undreaded and magical instrument of relief. And how far-reaching was this discovery of anæsthesia, how greatly has it extended the scope of surgery, minimized the pains of childbearing and the intensest sufferings in disease, and made humane vivisection and its vast consequent benefits to mankind a possibility! The name of Morton, in this connection, should be held in perpetual honor and gratitude, as one of the great benefactors of mankind." And so it will be the world over. Witness

what Sir Joseph Lister said in his recent presidential address before the British Association for the Advancement of Science (*British Medical Journal*, September 19, 1896): "This is the jubilee of anæsthesia in surgery. That priceless blessing to mankind came from America. It had, indeed, been foreshadowed in the first year of this century by Sir Humphry Davy. . . . But it was not till, on September 30, 1846, Dr. W. T. G. Morton, of Boston, after a series of experiments upon himself and the lower animals, extracted a tooth painlessly from a patient whom he had caused to inhale the vapor of sulphuric ether, that the idea was fully realized. He soon afterward publicly exhibited his method at the Massachusetts General Hospital, and after that event the great discovery spread rapidly over the civilized world." "The discovery of anæsthesia," says Sir Joseph, "inaugurated a new era in surgery. Not only was the pain of operations abolished, but the serious and sometimes mortal shock which they occasioned to the system was averted, while the patient was saved the terrible ordeal of preparing to endure them. . . . Anæsthesia in surgery has been from first to last a gift of science. Nitrous oxide, sulphuric ether, and chloroform are all artificial products of chemistry, their employment as anæsthetics was the result of scientific investigation, and their administration, far from being, like the giving of a dose of medicine, a matter of rule of thumb, imperatively demands the vigilant exercise of physiological and pathological knowledge."

It is fitting that the celebration of Morton's demonstration should take place on the very scene of his heroic exploit, according to a plan prepared by a committee of the trustees and medical staff of the hospital. Invited guests, we learn from our Boston contemporary, including the most distinguished surgeons of all countries and the benefactors of the hospital, will be received by the committee in the old amphitheatre, restored as far as possible to its condition at the time of the first operation under anæsthesia by Dr. John C. Warren. The public exercises will then be held in the new amphitheatre. They will include an address of welcome by the president of the hospital, Mr. Charles H. Dalton; papers entitled *Reminiscences of 1846*, by Dr. R. T. Davis, of Fall River, Massachusetts, and *Dr. Washington Ayer, of San Francisco; Surgery before Anæsthesia*, by Dr. John Ashhurst, Jr., of Philadelphia; *What Anæsthesia has Done for Surgery*, by Dr. David W. Cheever, of Boston; *The Relation of Anæsthesia and Obstetrics*, by Dr. John P. Reynolds, of Boston; *The Influence of Anæsthesia upon Medical Science*, by Dr. William H. Welch, of Baltimore; *The Surgery of the Future*, by Dr. Charles McBurney, of New York; and

*The Birth and Death of Pain* (a poem), by Dr. S. Weir Mitchell, of Philadelphia. The occasion will certainly be most interesting.

#### THE PLAGUE OF CITY NOISES.

THIS is the apt title of a very readable and forcible article, by Dr. John H. Girdner, of New York, published in the September number of the *North American Review*. Dr. Girdner takes the ground that noise is prejudicial to the continued health even of persons who are perfectly well, by interfering with their sleep; that in the case of those who are seriously ill it is sometimes sufficient to turn the scale against them; and that a considerable part of the noise of a great city is unnecessary and ought to be suppressed. He classifies city noises as follows: 1. Those produced by horses and wheeled vehicles. 2. Those emitted by peddlers, beggars, street musicians, and other persons—largely, we may add, whistling and yelling boys and midnight carousers. 3. Those caused by bells, whistles, clocks, etc. 4. Those proceeding from other animals than horses, such as cats, birds, etc. 5. Those that originate indoors, as from persons practising on musical instruments or training the voice. 6. Those given forth by explosives, mainly on the anniversary of the Declaration of Independence.

Dr. Girdner thinks that much might be accomplished by organized action in reducing the city noises, some of which, he properly admits, seem to be unavoidable; and he suggests that the most promising means of relief will probably be found in the formation of a society for the prevention of noise, on the plan of the Society for the Prevention of Cruelty to Animals and other like organizations. Much ought to be accomplished, it seems to us, through the agency of the board of health, for we take it for granted that that body has now a broader view of its powers and duties than it had a few years ago. The writer of this article knows of an instance in which a New York physician attempted, some fifteen years since, to induce a sanitary official to take some action to suppress the sounds of coarse and brutal revelry that nightly and nearly all night long poured forth from two bawdy houses situated in one of the most respectable neighborhoods. His effort was fruitless; he was told that, if he could prove that his health or that of some member of his household actually had been injured, some action might be taken, but nothing could be done in the way of prevention.

This particular form of nocturnal outrage has practically ceased in New York, but its cessation has been only an incident in the crusade against disorderly

houses, and not to any degree the outcome of a movement for the suppression of unnecessary noise.

We are glad to learn from the *Medical News* that the health commissioner of Milwaukee intends to stop unnecessary noises so far as he is able to do so, and we hope the New York board will not hesitate to make an attempt in the same direction.

## MINOR PARAGRAPHS.

### A CICERONE FOR THE MEXICAN MEETING.

DR. A. M. FERNANDEZ-YBARRA, of No. 235 Thompson Street, New York, has consented to accompany a number of physicians who intend to be present at the Mexico meeting of the Pan-American Medical Congress in November, and give them the benefit of his knowledge of the Spanish language. Gentlemen who would like to avail themselves of his services should communicate with him.

### A NEW TAPEWORM.

In the *Journal of the College of Science* of the Imperial University, of Tokyo, Professor Ijima, of Tokyo, and Professor Kurimoto, of Nagasaki, describe an enormous tapeworm which they modestly denominate *Bothriocephalus* sp. It measured ten metres in length and twenty-five millimetres in breadth at the broadest portion. Its expulsion was brought about with a dose of extract of male fern.

### THE SECOND SERIES OF THE INDEX-CATALOGUE.

THE first volume of the second series of the *Index-Catalogue of the Library of the Surgeon-General's Office, United States Army*, has recently been issued. It takes the vocabulary from A to Azzurri. It opens with a reprint of the first addition to the alphabetical list of abbreviations of titles of medical periodicals, from volume xvi of the first series. The plan and general appearance of the volume are identical with those of its predecessors, but we miss the familiar official letter from Dr. Billings, and there is nothing to show who has been charged with the preparation of the volume. It is to be hoped that the issue of these volumes will be made perpetual. Their value can not be overrated.

## ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 29, 1896:

DISEASES.	Week ending Sept. 22.		Week ending Sept. 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	49	6	29	6
Scarlet fever.....	26	3	50	3
Cerebro-spinal meningitis....	3	2	1	1
Measles.....	32	0	56	1
Diphtheria.....	135	11	142	26
Tuberculosis.....	181	116	155	106
Leptosy.....	1	0	0	0

**Changes of Address.**—Dr. Walter Lester Carr, to No. 68 West Fifty-first Street, New York; Dr. Egbert La

Fevre, to No. 52 West Fifty-sixth Street, New York; Dr. H. A. Powers, to No. 47 West Swan Street, Buffalo.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 20 to September 26, 1896:*

STRONG, NORTON, Captain and Assistant Surgeon, is relieved from duty at Fort Sheridan, Illinois, and ordered to Chicago, Illinois, for duty as Attending Surgeon and Examiner of Recruits in that city.

KULP, JOHN S., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Walla Walla, Washington, and ordered to Vancouver Barracks, Washington.

STEPHENSON, WILLIAM, Captain and Assistant Surgeon, is relieved from duty at Vancouver Barracks, Washington, and ordered to Fort Sheridan, Illinois.

A board of officers is appointed to meet at the Headquarters, Department of the Missouri, Chicago, Illinois, on Monday, October 5, 1896, at 10 o'clock, A. M., for the examination of such officers of the Medical Department as may be ordered before it to determine their fitness for promotion.

### Detail for the Board.

HARTSUFF, ALBERT, Lieutenant Colonel and Deputy Surgeon General:

LIPPINCOTT, HENRY, Major and Surgeon;

STRONG, NORTON, Captain and Assistant Surgeon.

The following-named officers will report in person to the president of the examining board appointed to meet at Chicago, Illinois, on Monday, October 5, 1896, for examination for promotion:

FISHER, HENRY C., First Lieutenant and Assistant Surgeon.

SHAW, HENRY A., First Lieutenant and Assistant Surgeon; KIEFFER, CHARLES F., First Lieutenant and Assistant Surgeon.

LAUDERDALE, JOHN V., Major and Surgeon, will, upon the arrival of KOEFFER, EGON A., Major and Surgeon, at Fort Crook, Nebraska, repair to his home and await retirement.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending September 26, 1896:*

LUNG, G. A., Passed Assistant Surgeon. Detached from the Vermont and ordered to the Naval Hospital, Chelsea, Mass.

WILSON, H. D., Passed Assistant Surgeon. Detached from the Chelsea, Mass., Hospital, and ordered to the Bache, Barbier, G. H., Passed Assistant Surgeon. Ordered to the Naval Academy.

JOHNSON, M. K., Assistant Surgeon. Detached from the Bache and ordered to the New York.

COOK, F. C., Assistant Surgeon. Ordered to the Vermont.

### Society Meetings for the Coming Week:

MONDAY, October 5th: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; Morrisania Medical Society, New York (private); New York Medicosurgical Society; Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vermont, Medical Association; Providence, R. I., Medical Association; Hartford, Conn., Medical Society; South Pittsburgh, Pa., Medical Society; Chicago Medical Society; Cleveland Medical Library Association; Monmouth, N. J., County Medical Society (Freehold).

TUESDAY, October 6th: New York Neurological Society; New York Obstetrical Society (private); Buffalo, N. Y., Academy of Medicine (Section in Surgery); Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Broome (annual), Columbia (semi-annual)—Chatham, Orange (semi-annual)—Goshen, and Washington (semi-annual), N. Y.; Hudson, N. J., Jersey City, and Union (quarterly), N. J., County Medical Societies; Androscoquin,

Me., County Medical Association (Lewiston); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

WEDNESDAY, *October 7th*: New York Academy of Medicine (Section in Public Health); Harlem Medical Association of the City of New York; Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Me., County Medical Society (Bangor); Bridgeport, Conn., Medical Association.

THURSDAY, *October 8th*: New York Laryngological Society; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; Medical Society of the County of Cayuga, N. Y.; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

FRIDAY, *October 9th*: New York Academy of Medicine (Section in Neurology); Yorkville Medical Association, N. Y. (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; St. Louis Academy of Medical and Surgical Sciences; Cleveland Medical Society; Medical Society of the Town of Saugerties (anniversary), N. Y.

SATURDAY, *October 10th*: Obstetrical Society of Boston (private); St. Louis Medical Society; Worcester, Mass., North District Medical Society (Worcester).

## Births, Marriages, and Deaths.

### Married.

KEELER—McCABE.—In Philadelphia, on Thursday, July 30th, Dr. Joseph Page Keeler and Miss Lizzie J. McCabe.

NORRIS—EDWARDS.—In Philadelphia, on Wednesday, September 2d, Dr. Elmer P. Norris, of Newcastle, Pennsylvania, and Miss Mary Edwards.

WIGHT—ROBBINS.—In Montclair, New Jersey, on Monday, September 28th, Dr. Jarvis S. Wight, Jr., of Brooklyn, and Miss Ida Pelham Robbins.

### Died.

GERHARD.—In Norristown, Pennsylvania, on Thursday, August 13th, Dr. Emanuel F. Gerhard, aged thirty-eight years.

FLEMING.—In Magnolia, Massachusetts, on Tuesday, August 18th, Dr. Andrew Fleming, of Pittsburgh, Pennsylvania, aged sixty-eight years.

HARRIS.—In Brantford, Canada, on Wednesday, August 26th, Dr. William T. Harris, aged forty-four years.

MATLACK.—In Downingtown, Pennsylvania, on Sunday, July 12th, Dr. William H. Matlack, aged fifty-nine years.

MILNE.—In New York, on Monday, September 28th, Dr. Charles Milne, aged fifty-six years.

ROSENTHAL.—In Chicago, on Monday, August 24th, Dr. Jacob Rosenthal, aged thirty-three years.

WALLIS.—In Arkadelphia, Arkansas, on Sunday, August 9th, Catherine, wife of Dr. J. C. Wallis, aged thirty-three years.

## Letters to the Editor.

SOME OF THE WORK ABROAD OF THE PASTEUR INSTITUTE BY ITS "MÉDECINS DES COLONIES EN MISSION."

No. 921 RUSSELL STREET, NASHVILLE, TENNESSEE.  
September 16, 1896.

To the Editor of the *New York Medical Journal*:

SIR: The pen of a lady that has instructed our profession in one of its branches of knowledge whose ap-

prehension by medical men is perhaps the occasion of the deepest despair of those who impart its principles, has enriched the pages of a magazine\* that has shown aforetimes a certain kindness toward doctors with an account of the parent institution and of some of its emissaries abroad. I must disclaim decisively the intention to treat familiarly the article in question, which is far beyond my commendation; while I confess that it has stimulated me to write out what I have seen here of late in sheer admiration of the results secured and in hopefulness of those almost sanguinely promised by current work.

The institute here is in charge of Dr. Lépinay, who administers personally the treatment of all patients bitten by rabid dogs, of which the quota of the tropical countries south of China is very large, there being no scarcity of them in China itself. Singapore has the most stringent regulations about the importation of dogs, the British fondness for which serves to keep one or more individuals under treatment here almost all of the time. I thought of Canon Wilberforce's objections to a Pasteur Institute in England—his belief in the immortality of the souls of animals†—in connection with a back-chilling ghost story ascribed to him by an acquaintance of his in Hong Kong, who declared it among his published works, as I looked into their carefully protected cell upon two big rabbits that had received subdural inoculations and that were definitely expected to die of hydrophobia at a time stated within quite narrow limits.

Their trephine wounds were scabbed, and their appetites were as little impaired, to all appearances, as if they had been awaiting a so-called natural death. Now, according to a principle lately enunciated by a titled individual of the same name as mine, in the setting of his profitable, "in-bred" style, each of these two specimens of a kind that is a marvel in the matter of reproductiveness has earned the funeral appropriate to the individual whose life it is considered to have prolonged. I have no hesitation in asserting that I fail to perceive wherein would lie the advantage, either to animals or to man, in making many of the days of the latter a succession of funerals to dead brutes; for I think that it is evident that fallible man can no more *prove* that any rabbit saved any man from the shocking death of rabies than he may that any one of an unrecorded number of slaughtered chickens prevented death by a timely frustration of some misadventure of nutrition. Furthermore, it appears to me that a fair examination of the statistics of the Paris institute, quoted in *L'Illustration* for March 7, 1896, ought to convince any one whatsoever of the effectiveness of Pasteur's treatment of rabies.

The completeness of the precautions against extraneous contamination in the inoculation of these patients is as bewildering to a non-technical observer as the latest improved Hoe printing-press in full operation would be to an ambitious country blacksmith. Dr. Lépinay has apparently had for long an interest in hydrophobia; and some of his statements about its incubation are full of great interest, although they require too detailed a statement for insertion here.

Another part of his employment is the superintendence of vaccine lymph. It has been produced from young buf-

\* Mrs. Grace Frankland, in *Longman's Magazine*, February, 1896.

† *Westminster Gazette*, 1894.

faloes (Fr. *buffle*; *Bubalus buffalus* (?) since 1891. Prior to that year, imported cattle and their progeny had never been made to yield a vaccine of anything like uniform strength. This experience has been corroborated elsewhere, and it has some relation, I think, to the important questions which various antitoxines suggest, the worst needed of which just now appears to be one for the plague the production of which is being retarded by some of these subtle things. The commercial tricks of the vaccine trade—so often exposed in the United States—have no place here. But, because the staphylococci are not encouraged to assist in the production of material to be sold, it must not be supposed that it is an experience altogether and invariably light to secure its protection. Confirming what I had been told, I was shown an opinion by the late Dr. R. Alex. Jamieson, of Shanghai, that did all in the power of honest and vigorous words to forestall that impression; which stated at the same time with the conclusion from his wide experience of its use—that there was little real need to seek further than this for a reliable preventive for small-pox—the fact that its manner of taking hold of a case was active and decided. I heard Dr. James Cantlie attack this vaccine, at the time of the Address to him in Hong Kong last February, with a warmth that surprised me as much I was soon amused by the nationally characteristic declaration following, to the effect that the law should protect the innocent and ignorant public from exposure to its dangers.

To leave no misapprehensions of my contriving after quitting this subject, I must state that I have never used the lymph under consideration myself, there being a squadron order for the Asiatic station that encompasses its prohibition; and that I may neither discuss nor disregard.

An unusual utilization of the supply is indicated by the following:

*“Ville de Saigon. AVIS: Tous les Landis à huit heures du matin, au porte du Marché, séance de vaccination et de révacination gratuite. Délivrance de certificat de vaccine.”*

This is repeated in Chinese characters, and in a local dialect given phonetically in Roman characters. There is no date whatever.

Speaking generally, one does not observe many “chop-dollar” visages—the results of small-pox, at least—among the natives he meets in these towns, who seem a rather short-lived folk and not unfertile in a reproductive way only. The absence of Lamb’s unkindly taking of small-pox is often remarked of the younger part of the population of Japan, in which progressive country there is organizing a centennial celebration of Jenner’s discovery.

If effective vaccine lymph were not yet in the echoes in my sensorium, I might be charged with the supererogation of commending Jenner, when my sole attitude toward him is one of undiminishable reverence for the hardness of head that enabled him to maintain, in the face of what no man may accurately weigh, the fact that the nut that he had found, like the most veritably blind pig, was the seed of the immortal oak, and not the vulgar chestnut, so prone to hide the uncleanly larva.

This laboratory was the scene of Calmette’s definitive researches upon the venom of serpents, which have yielded such results that one of his collaborators told me that he had heard it from Calmette himself that he

was unable to supply the almost universal demand for the antivenomous serum that bears his name. I, a native of Kentucky, was made the recipient, in trust for science, of a *flocon* of this serum, containing about twenty cubic centimetres, a dose *sub cute*, of course, for an adult. I shall have it tested on a case of the Loochoo Islands’ viper’s bite, about which two University of Pennsylvania men have lately collected some exact information. But it tried my frivolous soul to let pass the joke that was, as I had learned by much lamentable experience, not translatable; and, in witness of the fullness of my forgiveness of its sting, I send herewith a translation of Calmette’s appeal for venom. I have distributed this as effectually as I could in a personal way, in full view of its possible effects upon the demand for the older remedy for snake-bites, the profusion of Kentucky’s production of which has given to all her sons a reputation for the intemperance that they have made seductively easy for their neighbors. Calmette roundly declares it hurtful to those bitten by really poisonous snakes, a fact which I shall boast that I have long maintained. The explanation in order after this admission is that in its wild state the rattlesnake is not an infallibly deadly reptile, and that many recoveries are in spite of the treatment employed.

The most interesting of the very numerous interesting things that I heard in this connection was the case of cobra bite that was cured here. The subject was an Asiatic assistant in the institute, who was bitten on the naked hand by a captive snake. The antivenomous serum was at once used, along with the hypochlorite-of-lime solutions that Calmette recommends for neutralizing such unabsorbed venom as may have been excluded from the general circulation by a timely ligature about the affected limb. There was a good deal of local reaction, and a considerable tumefaction of the whole arm; but recovery was complete.

I saw two of these native assistants making an autopsy upon an enormous rabbit dead of hog-cholera, the ravages of which are extensive in this country. Some others were preparing some experimental media for the cultivation of the lepra bacillus just devised by Dr. Lépinay, who has devoted much effort to this subject; their “kitchen” was the most elaborately fitted one that I have ever seen.

I should be glad to forget the peculiar wickedness of expression that remained with the head of one of the largest cobras ever owned there; nor is the recollection of my feelings when Dr. Lépinay shook about fifteen grammes of dried cobra venom unpleasantly close to my nose an emotion to recall with fondness, notwithstanding his assurance that Calmette denies S. Weir Mitchell’s conclusion that it may be absorbed by intact mucous surfaces. It was just like *acacia*.

I came here to get a supply of antiplague serum upon the sufferance of Dr. Yersin, in order to test it upon the plague patients that are not becoming fewer to any encouraging extent at Hong Kong, being fully convinced that reasonable hopefulness may be expected only from some practical application of the antitoxic principles in such an hygienic wilderness as China. I had the great pleasure of being his guest at Nha Trang, a small village some two hundred miles from Saigon on the Annam coast. He is admirably equipped for work here; and this location was fixed upon by him, so as to avoid some of the dangers of a general infection that threaten from too familiar treatment of plague bacilli in a thickly settled place.

The production of the serum with which he was able to immunize and cure rats and some other small animals after their inoculation with the plague bacillus (*vide Annales de l'Institut Pasteur*, Paris, July, 1895) is a very slow and quite an anxious matter. The horses native to this part of the world have not as yet afforded quite the definite reactions after inoculation (or vaccination, according to Haffkine's nomenclature) with plague that were had in Paris; at the same time, they appear very susceptible to the various complications that this puissant organism invites. What he has obtained thus far, he considers too weak to try in a curative way upon human beings. It remains to be seen how the next lot produced will prove. Meantime, he has kindly ordered a supply to be sent out from the horse that yielded the best article in the experiments there.

A countrywoman of ours called my attention to the belief that she seemed to hold to the effect that in these efforts to cure a grievous scourge of humanity the will of God was being directly opposed. This suggested to me a new dilemma for the profession: if a patient dies of any malady whatsoever, as a matter of course his physician killed him; but whenever a person is either protected or recovered from an aforesaid difficultly curable and almost necessarily fatal—save for the treatment—malady, then must an impious medical attendant straightway repent, lest a worse thing befall him. It is surely not the least of the blessings of the science of today that such a question can no longer command serious attention.

Another subject of great interest that Dr. Yersin is investigating is cattle plague, which is very fatal to the native cattle and to buffaloes, hence a very effective bar to the extension of any bovine interests in the entire East. He is occupying himself with the organism that Metschnikoff demonstrated in the intestinal lesions constantly in that affection; but it is nothing like so satisfactory an object for experimental study as the plague bacillus (*Bacillus pestis*), which takes rank with the organism of anthrax and of diphtheria with regard to the definiteness of its cultural properties.

I learned briefly of Dr. Yersin's work in Madagascar last spring upon the hamaturia prevalent there, which the French call *biliuse hématourique*. He relinquished that investigation to Dr. Marchoux, another "médecin de première classe des Colonies en mission," at St. Louis, Senegal, whose future publications will be read with interest after Plehn's rather vague paper on the subject. Dr. Yersin spoke very confidently of his belief in the causal relation of a small bacillus present in pure culture in the urine and demonstrable abundantly in the glomeruli, with which he experimented for some time before resuming his work upon the plague. This seems to agree pretty closely with the results of the work a-doing for the committee on that disease for an interior medical society of ours, whereof by parcels I have something heard, but not intently.

The scope of the work indicated, which the genius of a single man has instituted and directed for a long voyage clear of every hazard whatsoever, would interest at some point the most carelessly idle drone alive; and not the least inconsiderable of its results will be, I think, an indirect one, the forcing of intrinsically less original nations to act in rivalry in this most humane field. Apart from the essential nobleness of the aims of its staff, which the triteness of worn-out phrases offers daily to most medical men; aside from the human sacrifices that its work has claimed, which weigh as feathers

in the estimation of calumniators who shriek untruthfully about the animals tortured because experimenters enjoy the infliction of torture upon them; there yet remains an establishment the efficiency of whose methods are among the greatest of modern achievements, and about which nothing that is discreditable may be said.

SAIGON, COCHIN CHINA, April 9, 1896.

*Supplementary Note.*—The publication of the foregoing has been most unconscionably delayed by circumstances for which no parties at present interested in it are in the least degree responsible.

In the interval that has elapsed, plague has declined for a second time upon the advent of hot and dry weather in Southern China after having extended its ravages to Amoy, Swatow, and Formosa; it is not fully ascertained that the sanitary measures instituted against it in the latter place by the Japanese have succeeded in arresting its spread. Reports from some other cities on the southern Chinese coast indicate its gradual spread where the fatalism of the people and their ignorance and absence of public spirit offer it no real resistance.

In a personal letter to me from Hong Kong of date July 21st, last, Dr. Yersin says: "Je pars demain pour Nha Trang après un séjour de quelques semaines en Chine. Je m'étais subitement décidé à essayer déjà cette année l'action du sérum antipesteux. C'est pour cela que je suis venu ici."

"J'avais reçu enfin de Paris une centaine de flacons de sérum antipesteux: j'en avais préparé moi-même un certain nombre à Nha Trang; et grâce à ce matériel, j'ai pu faire à Canton et à Amoy d'intéressantes expériences."

"Lorsqu'on s'y prend à temps et que la maladie n'est pas trop avancée, le sérum antipesteux a une action efficace très rapide et très frappante, mais il ne faut pas attendre pour traiter les malades que les accidents paralytiques du cœur soient commencés; car à ce moment là il n'y a plus rien à faire."

There has appeared an inconspicuous notice of these important results in one of the latest numbers of a prominent English weekly medical journal; and I am sorry to be unable to give the exact reference. I am glad to call attention to the fact that the same publication appears to regard the Pasteur Institute in India as one of the certainties to be evolved in the near future, and that its scope will not be confined to the treatment of rabies merely.

The *Saturday Review* of August 8, 1896, contains an account of a demonstration by Calmette of the immunizing power of his antivenomous serum before some sort of a commission sent to Lille from England; and the author of the notice inveighs mildly against some objections that have been urged, presumably, against its use which are based on the fact that the exact nature of the protecting agent is unknown.

My pleasure at these early and literal fulfillments of the predictions that conclude the above letter written at Saigon is completely negligible in the possession of these results of experimentation, which never could by any possibility have been reached by any other method; which have for the first time in the history of our earth afforded mankind a reasonable hope of assistance when suffering from hydrophobia, from cobra-bite, and from plague; and which take no account whatever of the great significance of Haffkine's peerlessly unselfish and arduous work in the long course of his anticholera inoculations in India, where, it is to be hoped, he will have many years of useful work in the Pasteur institute

to be established for him in spite of all bishops, canons, and other ecclesiastical authorities opposing.

*Passed Assistant Surgeon, United States Navy.*

#### ALBUMIN TESTING.

*CHICAGO, September 28, 1896.*

*To the Editor of the New York Medical Journal:*

SIR: In your issue of the 26th inst., Dr. E. H. Bartley charges error in certain conclusions which were published in the *Journal* of September 5th under the title of Albumin Testing. He avers that albumin, globulin and the albuminates are classed together as serum-albumin in my article. He takes exception to statements made regarding the selective action of the potassium-ferrocyanide test for serum-albumin, and also to the reactions as described of the sulphate-of-ammonium test for peptone. Replying to Dr. Bartley's exceptions, I would recommend a second and more careful perusal of the article in question. He will find no attempt to classify globulin, albuminates, and albumin together as serum-albumin, as he states. These bodies are considered separately, and the two former, for reasons set forth, are disposed of and specifically excepted from further participation in the procedures described. This is done to simplify the method and render it more eligible for practical clinical work. To consider serum-globulin and serum-albumin together because of their parallel significance and occurrence would be no unique view to take, since many authorities admit the first named to be mainly of theoretical interest at present.

Dr. Bartley has overlooked the following distinct statement made regarding the action of the ferrocyanide-of-potassium test: "It precipitates all modifications of serum-albumin, including the albuminates." This action is stated to constitute an advantage for the method for, I think, obvious reasons.

Regarding the action of the ferrocyanide test upon proteoses, the only member of this group precipitated by the reagent is protoalbumose, and in using the tenper-cent. solution of potassium ferrocyanide in the manner recommended the reaction is frequently indistinct and uncertain. Moreover, it is readily dissipated by heat, thus distinguishing it from that due to serum-albumin. This reaction was designedly not mentioned in my paper, as protoalbumose is a rare urinary product and of doubtful significance, consequently it would prove at present a more confusing than useful element in a practical clinical method.

Exception is also taken to my account of the reactions of the sulphate-of-ammonium test for peptone. This is evidently due to misconception of or unfamiliarity with the method I refer to. It will be found well described in Halliburton's *Chemical Physiology and Pathology* and in Purdy's *Practical Urinalysis and Urinary Diagnosis*. The following description is taken from Dr. Purdy's book:

"Saturate the urine (slightly acidulated first with acetic acid) with sulphate of ammonium and filter out any precipitate formed which may consist of albumin, globulin, protoalbumose, heteroalbumose, or deutoalbumose. Any proteid remaining may be precipitated by potassium-mercuric iodide or picric acid and can only be peptone [a positive reaction]. This is in fact the only certain method of identification of peptone."

The last brackets are mine.

I can indorse Dr. Purdy's recommendation of this test.

In conclusion, I repeat that the methods set forth in my article will be found to constitute a reliable, quickly applied, and easily available means for the detection and distinction of the proteids occurring in urine.

ARTHUR R. ELLIOTT, M. D.

#### Proceedings of Societies.

##### MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Twenty-second Annual Meeting, held in St. Paul on Tuesday, Wednesday, Thursday, and Friday, September 15, 16, 17, and 18, 1896.*

The President, Dr. HENRY O. WALKER, of Detroit, in the Chair.

**Cases in Renal Surgery.**—Instead of making a formal address, the PRESIDENT reported three cases of surgical affections of the kidney. He said that his experience in the fixation of movable kidney had been most satisfactory. In a case narrated, the kidney had been placed in its proper position and the capsule divided for a distance of three inches on its convexity, care being taken not to wound the cortical substance. The capsule had then been separated from the kidney for an inch entirely around the cut. The cut edges were fastened to the fascia and muscle, so that when the suturing was complete there was a solidity of fixation of the kidney. He did not use the deep suture through the substance of the kidney. The simplicity of the method commended itself both as to safety and as to a greater probability of permanent good results. The most practical route to the kidney was anteriorly. Fixation of a movable kidney is best done by stitching its reflected capsule to the muscles.

**A New Operation for Cleft Palate.**—A paper with this title was read by Dr. TRUMAN W. BROPHY, of Chicago. He took the ground that the operation should be performed much earlier than had been the custom. It had usually not been thought advisable to operate for the closure of cleft palate until the child has reached the age of from two to five years. He maintained that when the operation was thus postponed the changes in the voice had become permanent, and a repair of the cleft at that time would not react favorably in the voice production. His operation consisted in freshening the edges of the cleft; then, by deep suture of silver wire fixed through a lead plate conforming to the palate, the edges of the cleft were drawn together and so maintained until healing took place. The steps of the operation were minutely explained. It was original with the author and in his experience had proved most effectual.

Dr. W. H. DALY, of Pittsburgh, complimented the author on presenting a method so original. It did away with all the objections to the old operations, which in some cases one was compelled to do four or five times, and even then the result was never perfect, inasmuch as one could not at that late date teach the patients perfect speech.

**The Psycho-neural Factor in Clinical Medicine.**—Dr. C. H. HUGHES, of St. Louis, in a paper with this title, said the physician must consider the whole mechanism of the system when treating any one part. Some parts of the body influenced the whole less or more than others. The surgeon must consider the susceptibility, pre-

disposition, powers of resistance, recuperative powers, and natural courage of the patient in determining as to the prognosis or an operation. In any case the nervous system was either for or against him. Painful ovaries, neuralgic, congested, or inflamed, were not necessarily to be cut out, but to be cured by neurological treatment. The surgeons were beginning to recognize only those symptoms which came within their own legitimate sphere. He must have a wide neurological and psychiatric knowledge if he would avoid fatal mistakes. Much could often be done in palliation by tranquilizing neurological treatment. In fatal surgical results the reputation of the operating surgeon often suffered because of his having overlooked neurological conditions. Hope was itself a buoyant medicine, and faith in the physician or surgeon was a therapeutic power that should never be shattered.

Dr. BUCKNER of Cincinnati, said the paper was evidently the result of experience. A good surgeon must be hopeful, calm, and at all times careful to avoid anything disturbing to the patient already fearful of the prospects of an operation. It required but little observation for the good physician and surgeon to realize how important it was to be careful of every expression, act, and word in the sick room.

Dr. PARKER, of Cleveland, agreed with the writer, but said that, even with the aid of the neurologist, we were unable at times to make a diagnosis, and, indeed, there were many things in neurology that were not yet settled. The stress the author had laid upon the danger of intimidating the patient was right. It was desirable to anesthetize the patient in a side room. We knew the disadvantages of this as surgeons, but the advantages were very much greater.

**Trunk Anæsthesia in Locomotor Ataxia.**—Dr. HUGH T. PATRICK, of Chicago, read a paper in which he said that in nearly all cases of tabes dorsalis there was a band of anæsthesia about the trunk at the level of the nipple. Early in the disease it was very narrow or even incomplete, or might be represented by a zone in which the localization of touch is not normally accurate. The sensory blunting on the leg, so frequent in tabes, was generally an analgesia. The trunk anæsthesia was essentially tactile and the pain sense might be quite normal. The band of anæsthesia did not correspond to the cutaneous distribution of the intercostal nerves, but to the nerve fibres arising from adjoining segments of the spinal cord. In some cases there were two distinct zones of anæsthesia, indicating simultaneous involvement of spinal segments at some distance from each other. The borders were inconstant, ordinarily retracted on continued testing, and varied in position with the method of examination. The same band of anæsthesia might occur in syphilitic pseudo-tabes. The principal characteristics of the symptoms were illustrated by numerous diagrams and photographs.

Dr. HUGHES said it was not surprising that these peculiar areas of anæsthesia should be found in locomotor ataxia, considering that the entire symptom-complex of the disease was due to disturbance of the sensory mechanism. Organic disease might give expression to a latent hysteria, causing a combination of the two diseases. In locomotor ataxia there might be either anæsthesia and analgesia or hyperæsthesia and hyperalgesia.

**The Treatment of Some Inflammatory Diseases of the Gastro-intestinal Tract.**—Dr. GUSTAVUS BLECH, of Detroit, read a paper on this subject. He said that the

treatment of catarrh of the stomach and other similar inflammatory conditions of the organ, as it was practised to-day by most medical men, met with failure because it was directed against the symptoms and not against the cause of the disease. All the usual remedies might improve one or more of the symptoms for a limited time, but, the ætiological morbid conditions still remaining, the symptoms necessarily would appear again. His treatment was directed against the inflammation itself. He prescribed hydrozone, well diluted in water, at least a quarter of an hour before each meal. The oxygen which then developed killed the germs and cleansed the wall of the stomach without injuring the animal cells. It was an efficient and powerful, yet still bland and innocent remedy. He had seen the most stubborn cases of ulcer of the stomach end in recovery under the treatment.

Dr. DALY deprecated the very general use of glycozone, hydrozone, and other such remedies unless a very careful and discriminating diagnosis had been made.

Dr. PATRICK could not agree with the author until it was explained which variety of inflammatory condition in the stomach was referred to. Gastritis was too comprehensive a term. When a treatment was proposed we must know what form of gastritis we had to deal with.

Dr. I. A. ABT, of Chicago, said that diseases of the stomach could not be grouped together as gastritis. Many of these conditions were due to toxins found in the gastro-intestinal tract. We could not always make a positive diagnosis at once, but by experiment only could we arrive at definite conclusions. Any one remedy could not answer for all cases. Few writers deemed lavage of importance except as a diagnostic measure.

Dr. LARRABEE, of Louisville, said that almost any condition found in the stomach might come from the causes mentioned, but he was convinced that the portal circulation was a most important factor in these cases, and one, too, which was often overlooked. Exercise was of paramount importance in all cases of chronic gastritis. In arresting putrefactive changes in the stomach glycozone had proved in his hands most excellent, but he would not neglect to stimulate the liver when it was indicated.

**The Treatment of Experimental Tuberculosis in Animals by the Use of Blood Serum.**—In a paper thus entitled, Dr. PAUL PAQUIN, of St. Louis, said that the use of antitoxin went back to the active principle underlying immunization, an agent which is itself curative to a certain degree. Tuberculin was, to a degree, capable of modifying certain forms of tuberculosis. The inconvenience resulting was chiefly in the more or less severe reaction following. It was now maintained that tuberculin might be made with this poisonous principle eliminated. Experiments on guinea-pigs, unfortunately, did not give the same results as those made on the human subject. Furthermore, the experience of investigators with the serum treatment of tuberculosis varied greatly. They all, however, demanded of any treatment absolute cure of the tuberculosis when used on the human subject. We had been busy with all possible and varied forms of experimentation on the smaller animals, but we were not always able to properly interpret the results of any given form of treatment and then make an exact application of those principles to man.

Of guinea-pigs inoculated with tuberculosis and then treated with serum, ten per cent. were saved. Later

results showed a very much higher percentage than this. Antitubercle serum was positively curative in many cases; it had passed the experimental stage, but yet we knew it was not perfect. Only a certain proportion of tuberculous patients could, with our present knowledge of tuberculosis and antitubercle serum, be treated successfully.

Dr. LONGSTREET TAYLOR, of St. Paul, said it was not necessary that the serum should produce an antitoxine in the body. It would in many cases give most gratifying results, but in others, for some reason, it was disappointing. His experience with the Paquin serum had not been entirely satisfactory, but he would give it further tests.

Dr. I. N. LOVE, of St. Louis, had heard several papers on the most important subject by the same author during the past four years. Maragliano had recently published his work on the subject. The treatment was now almost beyond the stage of experimentation, but we must not be too hasty in our conclusion, for at least ten years' experience was necessary before anything would be positively and definitely known.

Dr. W. F. BARCLAY, of Pittsburgh, was satisfied that some such men as Paquin would demonstrate the ultimate success and positive value of antitubercle serum, and he hoped criticism would not discourage him and others.

Dr. H. W. LOEB, of St. Louis, remarked that at the last meeting he had presented some reports relative to the treatment of laryngeal tuberculosis with serum, and promised to report the results. While they had not been so good as he had hoped, yet they were such as to encourage still further attempts. Of the cases reported, in at least two the patients were yet living and well. As to two others he could not say, but at the latest reports there had been no return.

Dr. CHARLES GREEN, of St. Paul, said that the fallacy of medical statistics was best shown by tuberculosis. He had not much confidence in any such. Two centuries ago a cure for tuberculosis had been vaunted as infallible.

**Demonstration of the Therapeutic Action of the Antitoxines** was the title of a paper by Dr. E. M. HOUGHTON, of Detroit. The author reviewed the theories of serum therapy and demonstrated the differences between toxins and antitoxines.

(To be continued.)

## AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eighteenth Annual Congress, held in Pittsburgh, Pa., Thursday, Friday, and Saturday, May 14, 15, and 16, 1896.*

The President, Dr. WILLIAM H. DALY, of Pittsburgh, in the Chair.

(Continued from page 368.)

**A Case of Gunshot Wound of the Pharynx.**—Dr. D. N. RANKIN, of Allegheny, Pa., read the history of a case of such an injury. (See page 359.)

Dr. JOHN O. ROE said: A somewhat similar case came under my observation about eight years ago, that of a man about fifty years of age who had been wounded in the army. The ball entered the left side of the face, passed through the superior maxilla, and came out on the opposite side of the face in relatively the same location. In its passage through the jaw it carried away the palatine arch and the lower portion of the vomer,

leaving an opening through the hard palate about half an inch in diameter, which had remained unclosed; and through this opening a distinct view of the turbinated bodies and the interior of the nasal cavity was presented. The lower turbinated bodies were very much hypertrophied and afforded a beautiful illustration of this condition viewed laterally while *in situ*.

**The Control of Hæmorrhage in some Operations in the Nose and Throat.**—Dr. A. COOLIDGE, Jr., of Boston, read a paper on this subject. (See page 350.)

**A Case of Unusual Laryngeal Growth.**—Dr. J. W. GLEITSMANN, of New York, reported such a case. (See page 444.)

Dr. MAYER, of New York, said: I was much interested in this paper, as I had examined the patient when he was exhibited some time ago. No histological report had then been made and there was much question as to diagnosis. The remarkable point was the snow-white appearance of the mass, resembling the cauliflower excrescence seen on the base of the tongue and on the tonsils in mycosis. In view of the report here presented it would seem that further investigation would show that the patient finally succumbed to the disease.

Dr. C. C. RICE, of New York, said: I should like to know how deep this exudate extended, if it was an exudate at all. I am impressed with the many unusual cases we find that do not follow the ordinary course, the syphilitic and tuberculous growths and other similar affections. Microscopical examination is necessary to determine their true character. Perhaps the inflammatory exudate was the cause of the external appearance.

Dr. J. E. NEWCOMB, of New York, said: At the meeting of the academy to which Dr. Gleitsmann alludes in his paper no one was willing to make a diagnosis, although the majority thought it was syphilitic. With regard to the question of Dr. Rice, I think the iodide of potassium is a good thing. In many cases a malignant growth is surrounded by an inflammatory zone which will disappear under the use of the iodide. I think, therefore, it should be used and persisted in in order to clear up this zone.

Dr. G. V. WOOLEN said: I have never seen this whitish appearance but once, and that was in a case in the London Throat Hospital in 1886. The condition looked as if you were looking down upon snow-covered mountain crags that were standing close together. On removing a piece of the growth it proved to be malignant.

Dr. A. W. MACCOY, of Philadelphia, said: I should like to ask if the doctor has ever found anything resembling mycosis.

Dr. GLEITSMANN said: I have never found any symptoms of actinomycosis. Iodide of potassium had already been given to the patient. Applications with the cotton carrier, rubbing over the tumor, did not change its aspect. It was rather hard, more so than I expected, and required sharp and well-cutting forceps. Its excision proved to be not very difficult, and the hæmorrhage was slight. I am of the opinion that the patient will ultimately succumb to the disease, as the indications point to the tumor being malignant.

**The Sequelæ of Syphilis and their Treatment.**—Dr. CHARLES H. KNIGHT, Dr. J. E. H. NICHOLS, and Dr. W. K. SIMPSON, each read a paper on this subject. (See pages 379, 418, and 394.)

In reply to Dr. KNIGHT'S query as to how the plate was inserted Dr. KNIGHT replied:

About five minims of a ten-per-cent. solution of cocaine are first injected into the skin over the dorsum of the

nose, and the nostrils are sprayed with a similar solution. A short-bladed bistoury, with its cutting edge extending around its tip, is then introduced into the nostril, and the skin is carefully dissected from the nasal bones and from the anterior margin of the septal cartilage. A plate of platinum, which is said to be less irritating than aluminum, about a third of an inch wide and three quarters of an inch to an inch in length, with its edges and ends smoothed down and bent over, may be tucked into the bed thus prepared.

Dr. ROE said: The most serious cases of syphilis of the nose that I have seen have been in children, and were hereditary. In several of these cases the whole internal structure of the nose, both the osseous and cartilaginous portions, was entirely destroyed, the nose dropping in until it was flat with the face, while the skin was left intact. In one of these patients, a lad about eight years of age, the nasal bones were completely destroyed, and also the soft parts covering them, so as to leave an opening in the place where the nasal bones were, just below and between the eyes. In nearly all these patients the ulceration was still going on when I saw them, and attended with marked fetor.

In the majority of cases which I have seen in adults in which there was a deformity of the nose as the result of syphilis, it was due to abscess of the nasal septum caused by the syphilitic infection which destroyed the cartilaginous portion of the septum and thereby caused a dropping in of the anterior portion of the nose. It is this class of cases that most often come to us for restoration of the nose to its original condition or the removal of the deformity. Four years ago I presented a paper on the subject of corrections of deformities of the nose resulting from abscess of the nasal septum. In the majority of these cases the abscess was the result of a specific disease. These deformities I correct by subcutaneous flap operations. Notwithstanding the fact that the cartilaginous portion has been removed, all the soft parts are usually there, although in a distorted condition, flattened on top, and swelling out at the sides.

By raising the skin from the top of the nose and cutting these portions on the side which has become flattened out and turning them up over the top of the nose and holding them in place by either a pin or a clamp, a symmetrical nose may be obtained. Sometimes the cartilaginous portion of the end of the nose is unduly prominent. Thus in some cases it is necessary to lower it in the manner which I have formerly described for correcting the deformity termed "pug nose." This, of course, makes the nose smaller; but, as I described in my article on Pug Nose, the size of the nose matters little so long as the nose is symmetrical, for no two noses will be found to be exactly of the same size. A small, symmetrical nose will be handsomer and much more sightly than a large, unsymmetrical nose, and *vice versa*. In some of these cases, if the bridge of the nose is unduly prominent after the end of the nose has been made symmetrical, this angular prominence can be removed after the plan which I have described for the correction of angular deformity of the nose by subcutaneous operation. In many cases it is necessary to combine these different operations in order to bring about the desired result.

In the case of the lad that I mentioned, where the nose had been destroyed and an opening had been left in the top of the nose between and below the eyes, I restored this nose by using a finger after the method of Sabine, and had a very satisfactory result. Before this

operation the lad had a very repulsive appearance, so much so that people would shun him; but afterward the deformity was not markedly noticeable.

Dr. A. W. DE ROALDES said: I presume every one of us has come in contact with cases like those referred to. I have seen several where I would have given a good deal to have been able to restore the parts to their normal condition. I should like to see this question brought up at a future meeting. And those who have given much time to this subject should put their experience into systematic papers. I know of a case now where I could make a very large fee if I could only make a very good nose, but I have never felt sufficiently satisfied that I could do so to attempt or to recommend an operation. I have never seen cases which have convinced me that I should be justified in recommending an operation. As to syphilis of the nose, referred to by Dr. Knight, I must say I am not in favor of Rouge's operation in order to remove sequestra, as I think it is unjustifiable. There is nothing that can be better done by this operation than could be done by intranasal surgery. I have seen cases like those of Dr. Knight's, and in working on them I have had to use ice water in order to reduce the temperature of the burr or saw. By a little perseverance I have got through these exostoses. Very often the bleeding from the doctor's operation is very excessive. In my opinion, where you want to reach the nasal cavities, intranasal surgery should be the way to do it, drilling and holding the parts with strong forceps answering every purpose. Another thing, there will be no cicatrices in case you would want to do any other operation, while in the doctor's operation you will find considerable cicatricial tissue.

Dr. J. E. H. NICHOLS said: I will briefly describe three cases in which I have operated. In one case I attempted to put the nasal plate under the skin and on the nasal bones, the anterior end resting on the columna, and I wired it to the nasal bones. The principle was wrong, however, and an abscess formed on the bridge of the nose with subsequent falling in of the skin. This was due to the leverage pulling on the anterior end. In the second case the cartilaginous septum was destroyed. I attempted to build up the fleshy portion of the nose by putting in a saddle. This worked very well and brought the bridge of the nose into position. The saddle, however, was suddenly dislodged, and it was very hard to retain it in position, so I had to take it out. In the third case I used a method something like Dr. Hopkins's operation. It was a very severe case, as the patient had no nose whatever. The fleshy portion had sunken in and the face was much disfigured. I introduced a bridge through the side of the nose by incising at the nasolabial fold and carrying the ala over to the other side. The patient has worn this bridge for sixteen months without any bad results. The peculiarity about the case is that the cicatricial tissue had enveloped the arms of the bridge. There is a very slight opening in the centre and no breathing through the nose. The patient desires me to make an opening but I have refused.

Dr. E. FLETCHER INGALS, in discussing Dr. Knight's paper, said: With reference to ulceration of the cartilaginous septum, my experience differs from that of some of the speakers, for I have rarely seen ulceration of the cartilaginous septum that could be ascribed to syphilis, unless the bony septum was also ulcerated. I think it is unfair to assume that such cases are syphilitic, for I

believe this disease is not the cause in more than five per cent. of the cases. As a local application I prefer the strongest tincture of iodine. It was some years before I knew how to use iodides internally, and I am satisfied many failures occur in treating syphilis because the physician has not learned this lesson. I once had a case of syphilitic hypoglossic thickening in which I had to do tracheotomy. I had already given iodide of potassium in doses of twenty grains four times daily without avail; but after the operation, on the advice of the late Dr. Jewell, of Chicago, I increased the dose five grains each day until I was giving a hundred and twenty grains, largely diluted, four times a day. The effect was marvelous, and the thickening, of several months' duration, seemed to melt before my eyes and the lumen of the larynx became perfectly free in ten days. In giving large doses of the iodide of potassium, I gradually increase the dose, as in this instance, until the maximum dose is attained; this is continued for three or four days, and then the dose is reduced to twenty grains, which is steadily increased as before. The reason we often fail with the iodides is because we do not give enough.

Dr. W. P. PORCHER said: I recently saw a case in which there were tuberosities large enough to produce complete occlusion of the nose.

It has not been my experience that ulcerations begin in the cartilaginous portions of the larynx. I can not say anything about treating cicatricial contraction. As to general treatment, I know many syphilographers object to the combination of mercury and opium, but I have had very excellent results with it. I merely push to pyalism and not to salivation.

Dr. F. E. HOPKINS said: Dr. Knight's paper is especially interesting to me in its description of methods for overcoming the deformity due to loss of the bony framework of the nose. In selected cases, where sufficient time has elapsed since the initial lesion, I think the placing of a platinum framework—introduced after performing Rouge's operation—offers the best method for correcting the deformity.

In those cases which have received thorough constitutional treatment, and in which some years have passed since the appearance of active symptoms of the disease, the foreign body is tolerated with little irritation. Rouge's operation gives the opportunity for separating cicatricial adhesions and for the placing of the bridge so that no undue pressure is brought upon any part, and the careful molding and adjusting of the metallic bridge restores the individual contour of the nose.

I have done this operation twice, and while of neither case could it be said that nothing was left to be desired, the failure was due to the causes pointed out by Dr. Knight rather than to defect in this plan of operating.

In both cases there was satisfactory restoration of contour, but in the first one of the supporting arms of the bridge was placed too near the gingivo-labial fold and it gradually cut its way through this, so that its edge is visible upon raising the lip. It is fourteen months since this case was operated upon and the bridge is still worn comfortably by the patient.

In the second case the operation was done too early and it was necessary to remove the bridge after a few months. Both these errors could have been avoided by following the principles laid down by Dr. Knight.

Dr. HUBBARD said: Dr. Knight requested an opinion as to the special indications against the use of mer-

cury; and, further, gave the opinion that concealed caries, with retention of pus and debris, especially such as occurs in syphilis of cancellous bone, was a contraindication against mercury. Unless the necrotic tissue can be removed, and the carious area be cleansed thoroughly, iodides in very large doses is certainly the more rational treatment.

Dr. D. B. DELAVAN said: I have seen a case of total occlusion of the pharynx. In the patient referred to no artifice that was resorted to was able to show the existence of even the smallest sinus. Another thing to which attention should be called is hemorrhage, which, primarily or secondarily, is likely to occur.

Dr. KNIGHT said: I devoted much of my paper to Martin's bridge operation to the exclusion of other methods, as in cases in which it has been properly employed the correction of the deformity has been complete and the tolerance of the apparatus has been perfect. When the indications are followed, especially as regards the time of the disappearance of syphilitic symptoms, I believe that it will prove successful. I can not agree with those who regard Rouge's operation as a serious one, and under certain circumstances it is of service. I remember operating in a case of extremely large sequestrum of ivory hardness on which I could make no impression with a drill. Even the lithotrite was employed unsuccessfully. I do not think it has been shown that this operation is likely to induce any secondary or primary hemorrhage that can not be controlled by pressure. The disastrous cases of this operation have been those in which the sequestrum was high in the nasal chambers and was removed with difficulty, considerable violence being necessary. The space offered by this incision is somewhat disappointing. In the case I have just mentioned it was necessary to chip away a considerable portion of the maxillary bone. As to constitutional treatment, the principle which I have been in the habit of following has been to use mercury in late syphilis when it has not been given early. As Dr. Ingals has suggested, I have given iodide of potassium in large and increasing doses, being guided by its effects. The combination of mercury and iodide will sometimes be beneficial when either drug separately would have no effect.

Dr. NICHOLS said: I should like to ask Dr. Delavan if the case he referred to where there was no opening in the larynx has ever been reported?

Dr. D. B. DELAVAN said: In response to Dr. Nichols's inquiry, I would say that the case referred to has not been reported. Knowing the rarity of these cases, I tried every means to find an opening, such as endeavoring to force air and colored liquids from the nose into the pharynx. I have seen a number of cases where the opening was very small.

**Epithelioma of the Soft Palate removed by Injections of Liquor Potassæ.**—Dr. THOMAS HUBBARD, of Toledo, Ohio, reported a case. (See page 361.)

**A Case of Perichondritis of the Left Crico-arytenoid Joint from an Unusual Cause.**—Dr. H. S. BIRKETT, of Montreal, reported such a case. (See page 385.)

Dr. LEBLANC said: In view of the involvement of so many of the joints in the rest of the body by the rheumatic poison, shown by their redness and swelling, I should like to ask Dr. Birkett why it is not reasonable to suppose that the left crico-arytenoid joint was affected in a similar manner. It is not uncommon to find fixation of one side of the larynx (in my experience more often the left) in cases where no other history can be obtained than

that of rheumatism. These cases are not very often seen when acute, but then a swelling may be present as well as in acute arthritis elsewhere. If this supposition is correct, Dr. Birkett is to be congratulated on having seen an acute affection of a laryngeal joint caused by gonorrheal rheumatism.

Dr. BIRKETT said: The reason why I have called this a case of perichondritis rather than that of simple synovitis is because the synovial membrane being so intimately associated with the perichondrium, it is always involved in the same pathological process, and the disease perichondritis is the more generally recognized form of affection.

**Some of the Unusual Manifestations of So-called Catarrhal Laryngitis.**—Dr. C. C. RICE, of New York, read a paper on this subject. (See page 445.)

Dr. M. R. BROWN said: The case of the singer being in constant voice with a red condition of the vocal cords interested me, as I had a similar one under observation last winter. The man was suffering from an acute attack of inflammation of the upper air-passages with some hoarseness. The hyperæmia of the vocal cords was unusually pronounced. On calling his attention to this he said the cords were normally red. I applied the usual remedies for the relief of the coryza, pharyngitis, and laryngitis, and ordered rest for the vocal organs. In four or five days the acute symptoms had subsided and the treatment was discontinued, although the vocal cords continued of a red color. I examined the larynx again in two weeks and found it continued in the same condition of hyperæmia. Four weeks later it had not changed. During this time he was in excellent voice. The gentleman informed me he had been aware of his red cords for some years past.

Dr. H. L. SWAIN said: We must all have seen one or more such cases of chronically inflamed larynx. I remember seeing one where the cords were persistently red while the patient was in perfect voice. The case was in Germany and I could not believe it was possible for him to sing in that condition. I heard him in an oratorio that same evening, however, and I never heard such singing before. It was a most perfect basso voice. The condition was one of intense redness and an appearance of thickening, which was constantly present to my certain knowledge for at least a year, during which time I examined him on several occasions.

Dr. A. W. DE ROALDES said: I should like to corroborate what Dr. Swain has said. We have first to consider the quality of the voice, and it is quite common to see basso and barytone singers with red vocal cords. I recollect one of the most famous barytones, who had sung all over Europe, whom I was called to see in New Orleans some time since. I found the vocal cords very red and was about to advise a leave of absence for several weeks. I spoke to the manager about it, as he relied very much upon this artist, and I spoke to him the following day. I stated that the patient should not attempt to sing with such cords, when he told me that his cords were always red. This patient went through the whole season successfully. Another point we should bear in mind is the constitution of the patient. You may very often cure the coryza but the congestion will remain. Tenors or sopranos can not do so well in these cases as basses. Rheumatic and gouty affections also are important. Those artists usually rest during the summer, and almost invariably go to some watering place. Upon their return, in the fall, you will find the larynx clearer, but never completely clear.

Dr. W. K. SIMPSON said: I sometimes doubt whether it was ever intended for the human larynx to be used for perpetual singing, as there are so few singers who do not experience decided trouble. I sometimes think that singing is not the natural use of the voice. It is an acquired use. The other organs of the body would suffer in the same way from excessive use, taking the eye for example. I think the exception to this rule would be the remarkable instances. When we think of the number of thousands of singers and of the few who exceptionally retain their voices, we can not but wonder if it is not an unnatural use. The singing voice that could be retained indefinitely would be almost an abnormal production. The retention of the singing voice requires so much art, study, cultivation, and general condition of good health, that we must force ourselves to look upon the larynx as an organ which can not be overused with impunity.

Dr. NICHOLS said: The female voice partakes of this condition, and especially the alto. For six or seven years I have had under observation a variety-hall singer and when I first saw her I thought she had acute laryngitis, but at the end of several weeks the vocal cords were still very red, and after watching her for some time no change took place. I came to the conclusion that this was normal. She would come to see me when the cords were very red and would tell me that she was in perfect voice the previous night. I think the apparent congestion is possibly due to the muscular overexertion which she is compelled to resort to.

Dr. RICE said: There is a great difference between temporary congestions brought on by many causes and the permanent redness I have referred to. The doctor says his patient was a barytone. One of my patients was a high tenor and the other a soprano. I think these affections are sometimes congenital and sometimes are caused by physiological overaction. I have seen cases of congestion of the vocal cords in gouty and rheumatic patients, but I have never noticed any marked difference in the color of the two cords.

**Presentation of Instruments.**—Dr. E. FLETCHER INGALS presented a compressed-air apparatus consisting of a cylinder eight inches long by three inches and a half in diameter, strong enough to stand a hundred pounds pressure; one end of this is movable, so that when not in use the air pump and all the tubes and spray apparatus can be placed inside. The whole is inclosed in a leather case, which is made a little larger so as to provide room for a laryngoscope and medicaments. One object of this was to furnish a small apparatus that could be conveniently carried to a patient's house or to the theatre. Another object was to furnish our patients with an instrument whereby they could get a high pressure for making applications to the larynx, where it is often impossible to get a spray with an ordinary atomizer. With this apparatus it is easy to get forty to fifty pounds pressure, and it will hold sufficient air to treat three or four cases. This has a valve for the main air-conducting tube to prevent leaking, and where the tank is connected with the pump there is a bicycle valve and also an ordinary stopcock for the same purpose. In closing the movable head, when the clips are fastened by the fingers alone there is a little leakage, but this can be avoided by tapping them with a knife or bit of wood.

Dr. INGALS also presented a saw with an adjustable handle, which could be placed at any angle. The saw has two blades, one cutting forward the other backward. The instrument is so made that it can be boiled and kept

clean. Both instruments are made by Sharp & Smith, of Chicago.

Dr. CARL SEILER presented an instrument and said: This was suggested to me by the case of a certain clergyman of Brooklyn who died through inhaling a cork which lodged in one of his bronchi. It is in the form of a cork-screw, attached to a spiral wire covered by another spiral, which is wound in the opposite direction. It should be introduced by covering the screw. When *in situ*, by rotating, and by a slight twist of the handle, it will imbed itself into the tissue if it is soft enough. I simply devised this instrument for nasal surgery. I have several made longer, which are applicable for nasal work. An instrument like this can be readily introduced without the slightest difficulty, it being perfectly flexible.

Dr. JOHN O. ROE presented the set of instruments used by him for the correction of deviation of the septum. Since the time that he first presented these instruments they had been modified and improved so that he now regarded them as perfect.

Dr. ROE also presented an instrument for dilating contractions and strictures of the trachea, having a long curve similar to that of Grant's laryngeal guard forceps, but having two double joints, so that the lower joint of the instrument will dilate very much wider than the upper joint, which is accommodated to the larynx.

Dr. THOMAS HUBBARD presented a modification of Bosworth's nasal snare. The rider to which the wires are fastened is so made that it divides, and one wire (or both) can be drawn home at a time, thus giving the true *écraseur* or sawlike action. The strain upon the wire is much less than where both wires are pulled home together. The wires are made fast to the rider by eccentric levers so set that the grip tightens as the power is increased.

**Some Thoughts about the Prophylaxis of Nasal Catarrh.**—A paper thus entitled, by Dr. SEILER, was read by title.

Dr. J. W. GLEITSMANN, at the request of a number of members, showed Kirstein's autoscope, although a demonstration of the instrument without a subject must necessarily be very unsatisfactory.

The autoscope enables the observer to inspect the larynx directly without the aid of the laryngeal mirror, and is especially useful to obtain a good view of the posterior laryngeal wall and trachea, often also of the bifurcation, which parts are often difficult to see by the ordinary method. The vocal cord and the interior of the larynx can be plainly and distinctly seen, when sufficient pressure is exerted with the instrument to raise the epiglottis.

Dr. M. J. ASCH said: I should like to say that the work I have seen done with this instrument was marvelous, the view of the larynx was perfect. The patient shown by Dr. Gleitsmann had been trained so that the instrument worked very easily. A special advantage is the excellent view of the posterior walls of the larynx, and the diagnosis and treatment of this region can be made with wonderful effect. Operations can also be done with its aid, which adds to its value.

Dr. ROE said: A short time ago I had the pleasure of seeing Dr. Gleitsmann use this instrument, and the clearness and distinctness with which every portion of the larynx could be seen, and even the trachea as far as the bifurcation, were perfectly marvelous. The larynx could be seen as clearly and distinctly as if it were held up directly before your eyes and brilliantly illuminated. It was the most perfect illumination and the clearest

demonstration of the human larynx in the living subject that I had ever seen.

Dr. FRENCH, commenting upon the instrument shown by Dr. Gleitsmann, said: I was present when Dr. Gleitsmann demonstrated this instrument before the Laryngological Section of the New York Academy of Medicine and was much impressed with the remarkable exposition of the interior of the larynx and trachea which the instrument is capable of making. As the pressure on the base of the tongue must be very great I can not believe that it will be possible to use it in many cases. I should be glad if Dr. Gleitsmann would give us the results of his experience in regard to the proportion of patients on whom he has been able to use it.

Dr. A. W. WATSON, commenting on the instrument exhibited by Dr. Gleitsmann, said: I can speak of this instrument from the standpoint of the patient, as I have had it used in my own throat. I think the number of patients on whom it can be used is very small unless they have been previously trained. The pressure at the base of the tongue is very painful and causes an uncontrollable tendency to gag. The point of pressure was felt for an hour afterward.

Dr. S. SOLIS-COHEN said: Like Dr. Watson I can speak of this instrument from the standpoint of the patient, as my brother experimented with it on me. The sensation was not a very pleasant one, and before applying it to the average patient I should wish to thoroughly cocaineize the parts or to be sure that the patient's stomach was empty and that he had considerable self-control. However, the view that one obtains is wonderfully clear; and Dr. J. Solis-Cohen certainly manages to use the instrument readily without cocaine the first time he sees the patient. This I take it is due to his exceptional skill in manipulation. After getting this instrument my brother hunted up an old tongue depressor of his own, and found that by getting into the proper position he could obtain nearly as good a view, so that he need not have waited for this instrument if he had had the wit to look obliquely downward instead of directly forward. This instrument, however, is concave, while Dr. Solis-Cohen's was convex. The convexity is quite important. The principal point, however, is to have the instrument so curved that it pulls the tongue forward. The name is peculiarly inappropriate; one does not view his own larynx. Orthoscope would be better, as our ordinary method of examination might be termed *retrolaryngoscopy*; and this is the opposite.

Dr. INGALLS, continuing the discussion on Dr. Gleitsmann's instrument, said: I can not speak from the same standpoint as the other gentlemen. Would it not be possible that a little more curve in the instrument would enable us to operate under a general anæsthetic?

Dr. J. H. HARRMAN inquired if Dr. Gleitsmann had ever used the instrument for operative purposes. If so, with what result.

Dr. C. C. RICE asked if the instrument might not be of service in difficult cases where a definite diagnosis with the ordinary mirror was not possible. It might be that combined with a general anæsthetic it would be of service.

The PRESIDENT said it was difficult to understand how a man should give such a name to an instrument as that given to the one possessed by Dr. Gleitsmann. The name was in no sense indicative of its character or employment.

Dr. GLEITSMANN, in closing the discussion on Kirstein's autoscope, said that the instrument would never

supersede the laryngeal mirror or take its place. Although we could overlook the posterior laryngeal wall and see the trachea better with the autoscope, we saw in the majority of cases the anterior commissure less satisfactorily. Besides, there was a fair proportion of patients who did not bear the insertion of the instrument very well, some who did not tolerate it at all, also others in whom the introduction and inspection were impossible for anatomical reasons. A subject as good as he had had in New York, when he had demonstrated the instrument in different medical societies, was not found frequently. He admitted it was not easily borne, as he had found by having it used on himself, but it had been of good service to him in some cases where he needed a good view of the larynx. Up to the present time he had not used it in operations. An instrument with a curve would hardly answer the purpose, as the inspection had to be made in a straight line and pressure on the teeth had to be avoided. Dr. Solis-Cohen was correct in saying that the name was a misnomer. He had had the same idea himself and had mentioned it to Dr. Kirstein, who had stated, "It is my child, and a father can name his child what he pleases."

(To be concluded.)

## Miscellany.

**The Serum Treatment and Hydrophobia.**—In an editorial on this subject in the *Indian Medical Record* for August 16th, the writer remarks that in hydrophobia we have to deal with a living organism as the cause, although, until we know more, we can only speak of the virus. In our recognized protective treatment, inoculation, he says, this virus is injected along with the altered nerve tissue in which it grew, and the question arises, Does the attenuated virus act like vaccine, or like the attenuated microbe in anthrax, or may it not be that protection is given by the nerve tissue itself, which is in some way changed by the infecting virus? Pasteur himself held that in his injections of emulsions of infected spinal cord there was a virulent and a "vaccinating" element, the first of which disappeared much more rapidly than the second, during the drying of the cord. Practically, the writer continues, no new light has been thrown on the subject since Pasteur said that, and that hypothesis is singularly supported now in the treatment with the serum of animals which have been inoculated.

Bouchard conferred immunity on animals by injecting the fluid obtained by filtration from rabies-infected nerve tissue. Babes and Lepp succeeded with the same, after sterilizing it at 176° F., and the first trial of a serum treatment was also reported by Babes and Lepp. (*Annales de l'Institut Pasteur*, 1889, p. 384.) These authors threw the blood of inoculated dogs, and, of four dogs they had so treated, two survived inoculation "par trépanation." Rabbits were treated in the same way, after direct inoculation, and all were seen to have a much longer inoculation period than the check animals.

Following on this, says the writer, the experiments of Babes and Cerchez appeared (*Annales de l'Institut Pasteur*, 1891, p. 629). They had further found that the blood of immunized dogs had power of neutralizing the virus *in vitro*, and, encouraged by their experiments,

they had even gone on and applied the treatment to man. For this purpose they used serum obtained from the immunized dog and from inoculated man himself. In twelve cases they had so treated, there was one death, and they thus proved a value in the method, but showed it to be inferior to that of Pasteur.

Next came Guido Tizzoni and Schwartz (*Riforma medica*, 1892), with conclusions in support of this. They showed that Babes's results were only the less convincing because of the animal he had worked on. They themselves had found that to neutralize the virus *in vitro*, the blood of "immune" rabbits was much more active than that of dogs, and that the power of any such serum varied with the degree of inoculation undergone by the animal providing it. They had seen that if an animal came to die after prolonged survival by virtue of treatment, the virus in its nerve tissue was not attenuated, but would kill other animals after the usual interval. From this they had reason to say that the serum protected by acting directly on the organism rather than on the virus itself. They had also tried to isolate the substance to which a serum owed this protecting power, and they had found that it did not dialyze, that it was precipitated by alcohol like an "albumin," was very soluble in glycerin like an "enzyme," and was precipitated by sulphate of magnesium like a "globulin." At all events they had found that the blood of an inoculated animal contained this immunizing substance, which, isolated and injected in doses of from eighteen to twenty-five cubic centimetres for five or six days, would protect animals from the disease.

After that Babes and Talasescu (*Annales de l'Institut Pasteur*, 1894, p. 434), going on to establish this use of a serum, drew attention to the fact that the serum of inoculated animals had most preventive power in animals of the same species; that the serum of immunized rabbits, for instance, was above all powerful in the rabbit, and that of the dog in the dog.

And now, says the writer, we have the report of Tizzoni and Centanni, who have succeeded in obtaining a most powerful antirabietic serum. According to them, their serum is furnished by sheep, which during twenty days are submitted to inoculations with the attenuated nervous tissue of rabid animals in the proportion of 0.75 gramme to each kilogramme of weight of the animal treated.

They declare that one injection of their serum gives an almost immediate immunity. As a preventive, they say, a drop and a half of the serum is sufficient to protect an animal of two kilogrammes in weight inoculated an hour afterward with virus from the dog. As a curative means, the subcutaneous inoculation of a cubic centimetre is said to suffice, even eight hours after direct infection, that is to say, in the middle of the period of incubation.

This serum, they also say, can be dried and kept in bottles away from the light, and, so kept, it will remain powerful for a considerable time.

**Ichthyol in the Treatment of Tuberculosis.**—In the *Journal of the American Medical Association* for September 12th we find an abstract from the *Journal de médecine de Paris* for August 9th in which the writer, Le Tanneur, describes his experiments with ichthyol in order to determine its antiseptic power. He states that absolute sterility is secured with a five-per-cent. solution, although the shape of the Koch bacillus is altered and its development much retarded with a two-per-cent. solu-

tion and even a weaker one. He administered it to his patients in capsules (Chiron's) which contained four grains each in doses of from four to twenty-four a day. No effect followed the administration of six or eight capsules. M. Le Tanneur began with two capsules and increased the number to twenty a day, taken three times a day, during the meals. There is no necessity, however, says the writer, for so much caution now, as none of the fifty patients treated ever showed any inconvenience from its use, and several patients with complicating diarrhoea and gastric disturbances were found to be cured by it. The cough was much improved owing to the liquefaction of the sputa produced by the ichthyol, which also cured the congestion of the bronchial tubes. The color of the expectorations changed from green to yellow, then to gray, and finally to the ordinary color of mucous secretions, a long stride toward recovery, even in the minor point that they ceased to cause gastric disturbances when swallowed. The dyspnoea was relieved at once by the liquefaction of the sputa and the decreased congestion, which rested the heart and raised the general tone of the system. Pain in the intercostal regions was also much relieved, probably for the same reason. The general health did not show improvement as soon as with hypodermic injections of guaiacol, but it arrived and progressed none the less surely, and the patients gained flesh much more than with guaiacol. Several gained from seven to eight pounds in the first month, others gained four pounds, and two thirds of the patients showed a marked increase in weight. The sweats also diminished, but apparently only as the general health improved, as this effect was not noticed so promptly as with creosote or guaiacol. The appetite was not unfavorably affected as is frequently the case when guaiacol is used, but it was improved and restored to normal in many cases.

Le Tanneur concludes by stating, says the writer, that, while ichthyol is by no means the long-sought specific for this terrible disease, yet great benefit is derived from its use as a substitute for creosote and guaiacol, when, as so often happens, the system has become so habituated to them that they fail to affect it. It is especially indicated in bronchial tuberculosis, which it most promptly relieves. Its disagreeable odor renders the use of the capsule imperative.

#### Itrol (Silver Citrate) in the Treatment of Gonorrhoea.

—Dr. Oscar Werler, of Berlin, contributed to the *Berliner klinische Wochenschrift*, 1896, No. 37, an article on the use of this agent, introduced by Credé, in the treatment of gonorrhoea, and he has been good enough to send us a reprint of his article. The salt is made in Heyden's chemical works, in Radebeul. Dr. Werler states that in the course of about six weeks, in private and public practice, he has used it in at least fifty cases of acute or chronic gonorrhoea, in three of gonorrhoeal urethritis in women, in gonorrhoeal inflammation of the vulvo-vaginal gland, and in a few cases of chronic cystitis, with very favorable results. It is used as an injection in the ordinary way, also in irrigations according to Diday's method and by a modification of Janet's procedure consisting in washing the entire urethra with a lukewarm solution of the silver salt by means of a large syringe. In acute gonorrhoea, he prescribes at the outset a very weak solution, one of 1 to 5,000, and gradually increases the strength. The injections may be used four times a day. The solution should be kept in a yellow bottle. It is important that it should be re-

sorted to without loss of time, before the gonococci have penetrated deep into the mucous membrane. Even in very weak solutions, silver nitrate is an energetic antiseptic, disinfectant, and germicide. He sums up as follows: Itrol has an intense gonococcus-destroying action; it is readily borne by the urethral mucous membrane, and causes no noteworthy irritation or increase of the inflammation; its action is deep-reaching, but without injury to the mucous membrane; it therefore meets all the requirements of an efficient remedy for gonorrhoea.

**Uranium Nitrate in the Treatment of Diabetes.**—In the September number of the *Therapeutic Gazette* we find an abstract of a paper read by Dr. Samuel West, of St. Bartholomew's Hospital, London, at the last meeting of the British Medical Association:

Further experience during the last twelve months, he said, had confirmed the general results which he had stated in a paper read before the association last year.

The effects of the drug were (1) to diminish the thirst, (2) to reduce the amount of urine passed, and (3) to reduce the percentage of sugar. Like all the other drugs used in the treatment of diabetes, uranium nitrate did not influence all cases alike favorably.

The clinical investigation of the action of drugs in diabetes mellitus was not by any means an easy one. It involved time and care to eliminate the many disturbing factors in the results. In hospital cases he had taken the patients into the ward and kept them for some time upon diabetic diet, until the benefits derived from dieting, rest, and freedom from care and fatigue had fully shown themselves. As soon as the patient appeared to have arrived at a condition of equilibrium, the drug was administered, in small doses at first, which were afterward gradually increased. In private practice the results were not so conclusive, and the difficulties to be surmounted were often considerable.

Reference was first made to one of the cases recorded in last year's paper, that of Mrs. W., who had an attack of severe influenza, during which time the drug had to be suspended. The percentage of sugar, which had been very slight, rose during the influenza to between four and five, subsequently falling back again to about four. She did not resume use of the drug, partly because she did not appreciate the difference between three and four per cent. of sugar and practically none, and because the disease had not been cured by the drug, and for another reason—because she thought the medicine upset her digestion from time to time. She was now passing about three or three and a half per cent. of sugar, but in other respects was fairly well.

Among the new cases to be recorded in the present year, there were none which presented such striking features as those which had been published last year; still, several showed the same general improvement, though not in the same degree.

Case I was an instance of acute diabetes in a woman of twenty-two years. On admission she was passing ten pints of urine containing eight per cent. of sugar. After she had been dieted for three weeks in the hospital the amount of urine was reduced to four pints and the percentage of sugar from eight to six; but during all this time there were great fluctuations in the amount of urine and in the percentage of sugar, such as were usually seen in bad cases of diabetes. After her being placed upon the use of uranium nitrate, the doses being gradually increased to five grains three times a day, the

percentage of sugar had been reduced to four, the patient had greatly improved and gained ten pounds in weight, and the irregular fluctuations referred to had entirely disappeared. On her leaving the hospital a short time afterward the percentage had been three and a half and the quantity of urine three and a half pints. She had gone home to the anxieties and work involved in the care of a family of small children, had been unable to continue the dieting, and had, he believed, died not long after.

In the second case, that of a woman of forty-four, the patient had been passing seven pints of urine and seven per cent. of sugar, with considerable fluctuations between a maximum of 8.3 per cent. and a minimum of 6.5. After her being dieted in the usual way, the percentage had fallen to 6.8, and then uranium nitrate had been given, with the result that the percentage fell to 4.6. She had greatly improved in the hospital, and had continued to take the drug some time after she left.

The third case was that of a young man, aged twenty-five, with acute diabetes of short duration. He was passing, on admission, seven pints of urine, with a percentage of between six and seven of sugar. Ordinary diet produced but little effect upon the quantity of urine and not much upon the percentage of sugar. Under the influence of the drug the percentage fell from six to between three and four. Ten grains of the drug were taken three times a day without any inconvenience, the appetite remaining good and the weight increasing. Toward the end of his time he was allowed to have from four to six ounces of bread or toast. The use of the drug was continued, but under this diet the percentage rose only to four and a half—that is to say, not as much as might have been expected. He had been taking the drug now for a long time as an out-patient, was considerably heavier than when he was in the hospital, and was able to do his work well; and, although under irregular conditions of diet the percentage of sugar was heavier, still he believed the drug was a necessity to him, and he was much better and abler for his work while taking it.

The fourth case was that of a man aged fifty—a bad case of only six months' duration. The urine was about five pints, with six per cent. of sugar. He was dieted as strictly as possible, but could not be got to do without bread. The uranium was increased up to ten grains three times a day, which he took without any inconvenience, and he gained several pounds in weight. Under the combined action of the drug and diet the quantity of urine was reduced about a pint, the specific gravity remaining much the same, and the percentage fell rather more than one. The most marked feature about this case was that the irregular fluctuations, which had been so marked soon after his admission into the hospital, entirely disappeared, and the quantity of urine and sugar became fairly constant.

The last case was that of a private patient, aged forty-one, who had been the subject of diabetes for about four years. In this case the drug had not proved efficient. The patient had never been able to take more than about three grains three times a day, and while he was taking the drug the lowest percentage of sugar reached was 2.3. As long as he was under observation the percentage averaged about three before he began to take the drug. Before he came under observation the analyses had been made very irregularly, but it was stated that the percentage had on occasions been lower than this and that on some days sugar had been entirely

absent. These statements, however, the author could not vouch for. The drug, in the doses given, seemed really to have little or no effect, and, as the digestion became somewhat disturbed, it ultimately had to be suspended. The failure of the drug in this case might be attributed, the author thought, in some degree to the idiosyncrasy of the patient, who was unable to take any but very small doses, and even those for only a brief period.

The general conclusions that might be drawn from these additional cases were the same as those the author had expressed last year, viz.: that we had in uranium nitrate a drug of considerable value in the treatment of diabetes mellitus, though, like all other drugs, it could not be relied upon to produce equally good results in all cases indiscriminately.

**The Tri-State Medical Society of Alabama, Georgia, and Tennessee** will hold its eighth annual meeting in Nashville on Tuesday, Wednesday, and Thursday, October 13th, 14th, and 15th, under the presidency of Dr. J. B. Murfree, of Murfreesboro, Tennessee, who will deliver an address on The Doctor of Medicine. The following is a partial list of the papers to be presented: Convulsions in Children treated with Large Doses of Morphine, by Dr. Y. L. Abernathy, of Hill City, Tenn. (to open the discussion, Dr. P. D. Sims and Dr. G. Manning Ellis); The Theory of Antipyretics, by Dr. P. L. Brouillette, of Huntsville, Ala. (to open the discussion, Dr. W. C. Bilbro, Dr. J. W. Duncan, and Dr. J. B. Cowan); Cystitis, Report of Cases, by Dr. D. S. Middleton, of Rising Fawn, Ga. (to open the discussion, Dr. G. A. Baxter and Dr. George S. Brown); A New Splint for Fractures of the Humerus below the Surgical Neck, by Dr. G. A. Baxter, of Chattanooga (to open the discussion, Dr. C. Holtzclaw and Dr. W. F. Westmoreland); Humphrey's Operation (Amputation of the Penis), with Presentation of a Patient, by Dr. C. Holtzclaw, of Chattanooga (to open the discussion, Dr. Duncan Eve and Dr. Y. L. Abernathy); Diseases of the Veru Montanum (Caput Gallinaginis), by Dr. W. Frank Glenn, of Nashville (to open the discussion, Dr. William S. Goldsmith and Dr. J. A. Goggans); Operations for Abscesses of the Liver, by Dr. W. C. Towns, of Chattanooga (to open the discussion, Dr. W. E. B. Davis, Dr. Richard Douglas, and Dr. W. D. Haggard, Jr.); Acute Pelvic Congestion, by Dr. Valentine Taliaferro, of Atlanta (to open the discussion, Dr. W. G. Bogart and Dr. George R. West); A Few Unique Cases of Abdominal Section, by Dr. J. A. Goggans, of Alexander City, Ala. (to open the discussion, Dr. R. M. Cunningham and Dr. Richard Douglas); The Treatment of Pus in the Pelvis, by Dr. W. E. B. Davis, of Birmingham, Ala. (to open the discussion, Dr. R. J. Trippe and Dr. J. B. S. Holmes); Vaginal Hysterectomy for Bilateral Suppurative Processes of the Uterine Annexa, by Dr. W. D. Haggard, Jr., of Nashville (to open the discussion, Dr. Richard Douglas and Dr. J. A. Goggans); Some Remarks on Syphilis, by Dr. W. F. Westmoreland, of Atlanta (to open the discussion, Dr. Richard Douglas and Dr. W. Frank Glenn); Observations on the Treatment of Specific and Non-specific Venereal Ulcers, by Dr. William S. Goldsmith, of Atlanta (to open the discussion, Dr. George S. Brown and Dr. W. Frank Glenn); Bacteriological Data in the Drainage of the Peritoneal Cavity, by Dr. George S. Brown, of Birmingham, Ala. (to open the discussion, Dr. R. M. Cunningham and Dr. W. F. Westmoreland); A Statistical Report of Some of

the More Recent Remedies used in the Treatment of Tuberculosis, and a Summary of Recent Preventive Methods of Value, by Dr. R. H. Hayes, of Union Springs, Ala. (to open the discussion, Dr. R. M. Cunningham, Dr. H. Berlin, and Dr. J. C. LeGrand); The Turkish Bath; its Therapeutic Indications, by Dr. Louise Eleanor Smith, of Chattanooga (to open the discussion, Dr. E. A. Cobleigh and Dr. Katherine R. Collins); Microscopical and Chemical Aids to Diagnosis, by Dr. Katherine R. Collins, of Atlanta (to open the discussion, Dr. Louise Eleanor Smith, Dr. W. C. Townes, and Dr. G. W. Drake); Some Obstetrical Complications, with Report of Cases, by Dr. R. R. Kime, of Atlanta (to open the discussion, Dr. W. G. Bogart, Dr. Richard Douglas, and Dr. W. D. Haggard, Jr.); Puerperal Eclampsia, by Dr. Seale Harris, of Union Springs, Ala., and Dr. J. E. George, of Rockwood, Tenn. (to open the discussion, Dr. R. R. Kime and Dr. R. M. Cunningham); Medicine—Hippocratic and Operative, by Dr. John P. Stewart, of Attalla, Ala. (to open the discussion, Dr. J. B. Cowan and Dr. Y. L. Abernathy); The Diseases and Treatment of the Accessory Sinuses of the Nose, by Dr. B. F. Travis, of Chattanooga (to open the discussion, Dr. N. C. Steele and Dr. G. C. Savage); Diseases of the Eye, by Dr. Alec Sterling, of Atlanta (to open the discussion, Dr. G. C. Savage and Dr. B. F. Travis); Diseases of the Eye, by Dr. J. M. Crawford, of Atlanta (to open the discussion, Dr. Alec Sterling and Dr. T. Hilliard Wood); Report of a Case of Bradycardia, by Dr. W. C. Bilbro, of Murfreesboro (to open the discussion, Dr. J. R. Rathmell and Dr. J. W. Duncan); The Woodbridge Treatment of Typhoid Fever, by Dr. J. W. Duncan (to open the discussion, Dr. J. B. Murfree and Dr. J. P. Stewart); The Treatment of Cancer of the Skin, by Dr. C. R. Achison, of Nashville (to open the discussion, Dr. E. A. Cobleigh and Dr. M. B. Hutchins); and a paper by Dr. G. C. Savage, of Nashville (to open the discussion, Dr. B. F. Travis and Dr. J. M. Crawford).

**The Necropsy of a Parachutist.**—Mr. James Huxley and Mr. W. Jones Greer, of Newport, furnish the following to the *British Medical Journal* for September 12th:

Before submitting the facts revealed by the post-mortem examination a brief history of the accident will be of interest. On the evening of July 21st a girl, aged fourteen years, took her seat and grasped the hoop of her parachute to make her first attempt as an aeronaut and parachutist. The balloon, with the girl and parachute, rapidly rose to a height of between six thousand and ten thousand feet. She then jumped clear of the balloon, and came down swiftly for a distance of about three hundred feet before the parachute opened; it righted itself with a jerk and began to spin round. The girl was noticed to throw her legs about a good deal; there was a considerable amount of wind at the time, and the girl was carried over the river, into which she descended and quickly disappeared. She was attached to the parachute by clips, similar to watch clips, passing from each shoulder. A Board of Trade lifebelt was carefully secured round her waist. The body was found in about three days detached from the parachute; the clips were uninjured.

**Post-mortem Examination.**—External examination: discoloration of forehead between eyes, a large bruise over front part of left side of head above and behind the ear, an abrasion of skin over back of right forearm. The body was well nourished, but not fully developed. Cutis

auserina present. Tongue swollen and indented by the teeth, mouth and pharynx contained mud and sand. On dissection of the vertebral column no dislocation or fracture was discovered. No fractures or dislocations discovered anywhere. Internal examination: Thorax: the heart and pericardium normal in appearance, the cavities of the heart were found perfectly empty, the valves and endocardium smooth and healthy; the lungs were inflated, the pleural surfaces of the left were adherent almost all over, on the right normal; diaphragm normal. On opening the trachea it was found to contain mud and sand, the small bronchial tubes were found to contain mud, sand, and froth. The oesophagus was empty. Abdomen: liver congested; on opening the stomach it was found perfectly empty; there was a small cicatrix on the posterior surface near the cardiac orifice.

On consideration of these facts we considered ourselves justified in coming to the conclusion that the girl was probably in a state of syncope when she reached the water, and that death was due to drowning.

**The Late Sister Superior of the New York Foundling Hospital.**—At a special meeting of the medical board, held on September 15th, action was taken as follows:

The medical board desire to pay tribute to the memory of Sister Mary Irene FitzGibbon, late superior of this institution. Several members of the board have served for more than twenty years, and have witnessed the growth of this work, its transfer to larger buildings, and its full development. They recognize the fact that the one person who organized, who procured friends and funds, who planned and built the one great foundling hospital of America was Sister M. Irene. Whatever other forces and agencies were assisting, it has been obvious to all that the central figure, the persuasive, tactful genius, the sweet-souled woman who led to this success was she to whom to-day the medical board pay this parting tribute.

Whereas, The medical board, in the death of Sister M. Irene, the sister superior of the hospital, have lost the first executive officer and long-tried friend—therefore be it

*Resolved*, That the board cause to be spread upon the minutes of its records these resolutions of appreciation and sorrow, incorporating the words "This board has lost the best friend any hospital board ever had."

*Resolved*, further, That the sympathy of the board be extended to the Reverend Mother Superior and the Sisterhood of the Sisters of Charity, also that a copy of these resolutions be forwarded to them and be published in the current medical periodicals.

J. LEWIS SMITH, M. D.,

[Signed] J. O'DWYER, M. D.,

GEORGE F. CROFT, M. D., *President of the Medical Board.*

**The New York Academy of Medicine.**—The special order of the meeting of Thursday, the 1st inst., was a paper entitled Practical Points regarding the Senile Insanities, with special reference to Prophylaxis and Management, by Dr. Ralph L. Parsons.

The next meeting of the Section in Paediatrics, on Thursday evening, the 8th inst., will be a "clinical session." The following topics are announced: Congenital Stenosis of the Pulmonary Valves; a Cardiac Case with Unusual Symptoms; Progress in the Treatment of Cases of Cretinism (by Dr. Henry Koplik); Progressive Muscular Atrophy; and Arthritis Deformans (by Dr. William L. Stowell).

## Original Communications.

### FURTHER NOTES ON THE PATHOLOGY AND TREATMENT OF GRAVES'S DISEASE.

By W. H. THOMSON, M. D., LL. D.,  
PROFESSOR OF THE PRACTICE OF MEDICINE  
IN THE NEW YORK UNIVERSITY.

(First Article)

In an article on Graves's disease, published in the *New York Medical Journal*, June 3, 1893, I advocated a view of its pathology, with treatment corresponding thereto, which I would wish to supplement now with the details of twelve other cases occurring since in my private practice, which seem to me to corroborate the positions then taken. In a disease whose pathology is so much controverted and in which hypotheses are so easily made, it seems worth while to let therapeutics have a place in suggesting the true nature of the complaint, if there seems to be any marked effect, as I think there is, upon the course of the disease by dealing with it according to certain principles of treatment. As we sometimes give mercury or potassium iodide to test a provisional diagnosis of an affection as probably due to syphilis, so I would now rely upon the results of a certain definite course of treatment to determine whether a given case be one of Graves's disease or not. I do so because, as stated in my former communication, I object to the name exophthalmic goitre, owing to its derivation from symptoms either not necessarily present in unquestionable cases of the affection, or of uncertain duration and degree when present. This name, therefore, operates to attract undue attention to certain non-essential, because variable, developments in the disease, and thus diverts inquiry from the more causative elements in its pathology. Moreover, for the same reason, this name often prevents a correct diagnosis, so that the disease may go on to a fatal termination without its nature being recognized, because the patients have neither exophthalmia nor goitre, while in others it is allowed to progress without the treatment which is so effective in the early stages, until the late development of engorgement of the thyroid gland reveals the true character of the affection.

I first attempted to show that the most constant elements in the course of Graves's disease are: 1. Digestive disturbance, culminating in severe cases in marked emaciation without fever, and in the majority with a tendency to persistent diarrhoea. In a large proportion these digestive disorders are peculiarly attended with a variety of sensory and motor symptoms in different parts of the body, such as neuralgic pains, disturbance of the special senses, local paralyses, etc. 2. Continuously rapid action of the heart, with dilatation and throbbing of the arteries. 3. Muscular tremor, both local and general, as

if from emotional excitement, not infrequently in advanced cases accompanied with a tendency to falling. 4. General nervousness, with occasional affection of the disposition and even of the mind. 5. Irritability of the bladder, especially at night, and in many cases with itching of the skin, profuse sweats, and other vasomotor symptoms. 6. Falling out of the hair. 7. Progressive weakness, often very noticeable in the voice, with a tendency to death from exhaustion of the heart owing to its long-continued overaction.

Now, in considering the pathology of this affection, it is certainly significant that all of these symptoms may be present and go on to a fatal termination without either exophthalmia or goitre being observed, or in some patients not till late in the course of the complaint. When this happens they are then pronounced to be cases of Graves's disease when they should have been recognized and treated as such long before. This surely is not a satisfactory position, either as regards pathology or anything else. If enlargement of the thyroid and protrusion of the eye must be in evidence ere we can pronounce a case to be one of Graves's disease, then, as regards pathology, we may properly turn our attention wholly to the thyroid gland as the subject for investigation, as we do with the kidney in Bright's disease. Then, for those who die after presenting the same general symptoms, but without goitre or exophthalmia, we must either class them as belonging to some other not yet named affection, or else frame theories how Graves's disease may exist without the thyroid being appreciably affected. But if so, when can we be sure whether a given case, no matter how serious, is a case of Graves's disease or not? The first case detailed in my previous communication fully illustrated this difficulty, as the patient never had any protrusion of the eyes or any enlargement of the thyroid until a short time before her death, when, on her third relapse, the goitre became quite pronounced. I have now another similar fatal case to report, which is as follows:

On November 30, 1893, I was asked to see Mrs. P., of Clifton Springs, N. Y. She was forty-four years of age, with a not very favorable family history, one brother at present suffering from Addison's disease. It was stated that she had been feeling ill and greatly debilitated all summer, though complaining most of all of extreme nervousness. She also noticed that "her hair was all coming out." For three weeks past she had grown much worse and had a constant diarrhoea with great irritability of the bladder, and a tendency to fall, from her knees suddenly giving way if she stood up. She had had intermittent albuminuria, which, as Dr. Beybie first showed, is common in Graves's disease. I examined her urine several times and found the specific gravity 1.020 to 1.025; of natural color, with no albumin and no casts. Temperature, normal; pulse, 120 to 130, weak. There was general throbbing of the arteries, most marked in the carotids and femorals. The most serious feature of her case, however, on my first visit, was recurrent attacks of uncontrollable vomiting along with the diar-

rhœa, which, on December 2d, could hardly be checked by any remedies.

*December 4th.*—The pulse became more rapid, and there was constant nausea with fits of fainting.

*7th.*—Stomach and bowels still very irritable. The patient now became wandering in her mind, with maniacal hallucinations and extremely restless. She could not be prevented from getting out of bed for the movement of the bowels, though when she did so her pulse would become very irregular. On December 10th, while doing so, she suddenly fainted and died.

Now, in this rapidly fatal case—in which, on account of the persistent vomiting and diarrhœa when she applied to me, no treatment of the disease, either dietetic or medicinal, was practicable—the symptoms are in complete accord with other histories published by various authors of acute Graves's disease, mania being particularly noted as of bad augury. But because her physician had never noticed in her either exophthalmia or goitre, he had never thought of her having Graves's disease, and afterward he wrote to me that he had little doubt that his own wife had died two years before from the same affection, as her symptoms were identical with Mrs. P.'s. As Gowers remarks, "If preponderant cardiac disturbance makes rapid progress, the patient may die before other symptoms (of the thyroid and the eyes) attain such a degree as to attract attention." We think that it is time that such symptoms should of themselves attract attention instead of our acting in the case of Graves's disease like a physician who would never suspect that a patient had Bright's disease unless he were markedly dropsical.

Interpreted aright, clinical evidence is as good as any other evidence in affording indications which bear upon pathology, and for that reason I would submit the following histories:

**CASE II.**—In this case I was myself misled at first by the insidious onset of the complaint and by the predominantly nervous symptoms of the patient, which I regarded as natural to her, as she belongs to a markedly neurotic family, one brother being insane as well as phthisical. I was first consulted by Miss M. W., aged forty-five years, for a peculiar pain occurring on the anterior aspect of both thighs at night. She had been troubled much with gastric disorder, which I was inclined to attribute to previous frequent attacks of hepatic colic, with jaundice, in 1891 and 1892. After a variable experience of the above-mentioned recurrent pains throughout the summer of 1893, she consulted me on December 9, 1893, for a constant throbbing in her left ear and for trembling of the right arm. This shakiness of the arm increased by January 6, 1894, with a sense of inward trembling as if she were frightened. By February 18th the tremor of the hand had so increased, especially on waking in the morning, that she had to postpone writing any letters till evening. Tremor had also extended to the muscles of the face, especially in beginning sentences when talking. Meantime the throbbing in the head was distracting, and she was greatly troubled with insomnia on that account. It was then that I first noticed that her pulse was beginning to be quite rapid, and ere long the continued rate

between 120 to 130 led me to regard the case as one of beginning Graves's disease. One peculiar symptom was complete and permanent anosmia, following several attacks of epistaxis, which had been preceded by severe headaches. These headaches would yield to nothing but drachm doses of fluid extract of ergot, and closely resembled her old attacks of migraine, from which she had been quite free for a number of years. To make a long story short, on March 17, 1896, the note is, Goitre at last! This enlargement of the thyroid, with some moderate protrusion of the eyes, developed quite rapidly, and, curiously enough, after the treatment for Graves's disease during nine months previously had markedly relieved her other troubles, the pulse having fallen to 82, the nocturnal neuralgias and the tremor having almost disappeared, and, what she most appreciated, the throbbing in the ears having ceased. This goitre (July, 1896) still remains, but varies so that she cares little about it.

In this case the order of development was first, gastric disturbance, then sensory and vasomotor symptoms, then tremor, then, after a year, tachycardia, and, lastly, after nearly three years, goitre and exophthalmia.

**CASE III.**—This case is of interest on account of the advanced stage of the disease before the treatment which I recommend was begun. Dr. J. C. Thompson, of Pittsburgh, Pa., having read my article which had been copied in the *American Ophthalmological Journal*, wrote to me that he had a brother who was suffering from Graves's disease, and asking for some further particulars about treatment. I answered his letter accordingly in November, 1893, but not hearing any further about the case, I wrote in March, 1896, to ask if he had tried the treatment, and with what results. I append his reply in full as a corroboration from an independent witness of the good results which I have found in practice from dealing with this affection as primarily due to the absorption of intestinal ptomaines.

"524 PENN AVENUE, PITTSBURGH, March 9, 1896.

"My brother at the time I wrote you had had the disease two years, having lived in Helena, Montana, at an altitude of four thousand five hundred feet above sea level, for most of the time. Some two months before I corresponded with you he had returned to his home in this city for treatment, being thoroughly broken down. His Helena physician thought he would not live a week longer if he remained in that city. On his return he went under treatment instituted by myself and also two other physicians of eminence in the regular profession. His weight had fallen off from a hundred and sixty-five to a hundred and twenty-five pounds; his pulse varied from 130 to 150; the thyroid gland on the right side was greatly enlarged; he perspired copiously on the slightest exertion; the hands trembled; the breathing was labored and audible; the voice weak and husky; his bowels were loose, there being five or six movements in twenty-four hours, and in connection with this condition he had a ravenous appetite; he was compelled to void urine three or four times a night; had an unnatural gaiety of manner, and, in brief, presented a perfect clinical picture of a typical case of Graves's disease. Under the treatment suggested by the two physicians spoken of and by myself, which consisted of heart sedatives and "tissue builders," he went from bad to worse steadily, until his weight was not over one

hundred pounds, and he could scarcely stand up. At this time I heard of the results secured by an eminent medical gentleman in New York, Dr. Rockwell, by the use of electricity in the disease (published in the *Medical Record*), and as a last extremity took my brother on to see this gentleman. He gave a guarded prognosis, and thought I had better take my brother home, which advice I followed. After this there was a rapid and constant decline in the condition of the patient, and none of the physicians who saw him thought there was any hope of his recovery. At this time I read the article you had written and commenced the line of treatment suggested at once. In my notes, taken at the time, I found that the following was the condition of the patient the evening before the dose of calomel was given, preliminary to the treatment to follow. Pulse at 8 p. m., 146; respirations, 30; temperature, 99°. Following the dose of calomel the pulse dropped to 104 the next morning, the lowest it had been since I had seen the case. The line of diet suggested by you in your article and letter was strictly followed, and an immediate and unmistakable improvement in all the symptoms followed. This was continuous, so that at the end of two months there was a gain of twenty pounds in weight, at the end of six months a gain of forty-six pounds, and corresponding improvement in all the other features of the case. The pulse generally remained about 104 to 110. At the end of six months the patient then went to southern California to escape the severe winter here, but, not having the chance to get the diet regularly, he did not improve much there. After a residence of five months there he returned here, and has continued the diet and treatment without variation or cessation ever since, so that at the end of two years and a half his condition, as represented by general signs, is, March 6th: Pulse, after exercise, 90; respirations, 22; temperature, normal; weight, one hundred and forty pounds; bowels regular, one movement in twenty-four hours and normal; skin congested about ears and neck but natural otherwise; appetite good; sleeps well; has no pains; wants to go into business; eyes still unduly prominent, but not so much exophthalmia as formerly. The von Graefe sign absent, except when excited. The thyroid enlargement is as great as ever; is comparatively strong; walked six miles the other day without undue fatigue. He is satisfied to continue the diet and treatment indefinitely, feeling certain that his life was saved by the treatment, as I do and all the other physicians who saw him."

CASE IV.—Miss L. W., aged thirty-five years, teacher in a public school of this city; called first on May 22, 1893. Her aspect then was like one in the last stage of phthisis, as regards extreme emaciation and anæmia. Eyes somewhat prominent, but no von Graefe or Stellwag symptoms. Thyroid uniformly but not considerably enlarged. Hair much thinned; much tremor of the hands; voice tremulous and weak; ataxia just beginning, as she had had her first fall that day. Heart action tumultuous but without murmur. Pulse, 152; has been greatly troubled with diarrhoea for nearly two years, and latterly with much bladder irritability, also itching of the skin and persistent insomnia. Meantime she has become so weak that she feels as if she might die at any moment. The patient was with difficulty removed to her father's house in the country, where she followed out the line of treatment recommended.

July 19th.—A letter from her mother states that she is greatly improved from the dying condition she seemed

in upon her arrival at home. Her diarrhoea is checked, and her sleep is much better.

August 19th.—The patient was able to write herself; movement of the bowels still too frequent.

November 17th.—Writes that she is steadily gaining in flesh and strength, but that the goitre and exophthalmia still persist; bowels move three or four times a day, but the movements are not diarrhoeal; the itching continues, but she sleeps well.

February 3, 22, and March 22, 1894.—Slow but continued improvement, except that she has returns of old migrainous symptoms, and the vesical irritability continues.

May 18th.—She returned to the city and presents a striking contrast to her appearance a year before, being now quite full-faced and with a natural healthy appearance but for her moderate exophthalmia. Pulse, 124; rather high tension. Bowels move twice a day, but are not loose. Had to have her hair cut, as it was falling out so.

June 29th.—Still feels that she is gaining, but pulse, 126; high tension. Bowels, however, inclined to looseness if she modifies her diet at all; itching still troublesome.

September 22d.—Patient able to resume her duties at school. Looks well. Pulse, 114. On August 2d had a bad fall, previously having for two days felt a weakness in the knees. Through October and November continued to hold her own in much the same condition.

January 5, 1895.—Better; but can not change her diet without soon having a return of her old symptoms. Through the winter attended well to her school duties.

May 18th.—For the first time pulse down to 100.

June 18th.—Gaining in flesh and strength; pulse, 88; bowels now inclined to constipation.

October 18th.—Has felt practically well all summer and since resuming teaching.

February 22, 1896.—Had some relapse of diarrhoea and rise in the pulse, with return of bladder irritability, from taking fruit.

On resuming her milk diet and taking the medicines she was soon better again.

June 20th.—Patient considers herself about well.

CASE V.—Miss M. P., aged twenty-three years, May 27, 1893, daughter of a wealthy manufacturer in northern New York. For some six months has had a great deal of palpitation, along with thyroid enlargement. Pulse, 146; tremor moderate in the hands; strong mitral murmur present; very nervous and inclined to insomnia. A singular feature in this case was that she had complete Bell's paralysis of the right facial nerve, preceding by a year her goitrous symptoms, but it passed off in a few weeks; but, after recovering entirely from the symptoms of Graves's disease in 1894, she came again, September 10, 1895, with completely developed paralysis of the left facial nerve, which persisted in spite of persevering treatment for nearly four months, the last note on January 25, 1896, being: "The only sign left is a raising of the lip when she closes the eye; also, she can not whistle." This patient often suffered from migraine. No rheumatic history nor chorea; mitral murmur still (1896) present, otherwise health good.

CASE VI.—Patrick S., aged twenty-four years, gardener, son of healthy Irish parents; first came under treatment April, 1894. Had always been healthy and of temperate habits. For no reasons he could account for he began to feel excessively nervous, tremulous, and troubled with insomnia and palpitation. He was also

becoming prematurely bald, and so weak that he could hardly stand. Emaciation was also becoming very pronounced. Pulse, 120 to 140; moderate exophthalmia, and very variable goitre. He improved greatly under treatment until October, 1894, when he had a severe relapse, caused by emotion on the death of his mother. After that, by rest and being more attentive to his diet and treatment, he has gained flesh again. Present state, June, 1896, nearly well; still some goitre.

CASE VII.—Mrs. B., wife of a physician. Her husband reports to me on February 13, 1896, that I prescribed for her for Graves's disease five years ago. She then had pronounced exophthalmia but no thyroid enlargement, nor ever has had any. She was ordered then to take the fermented milk and scarcely any medicine. The tremor of the hands at that time was so great that she could not handle a tumbler of water. She lost her hair to a great degree, and she fell in weight from one hundred and thirty to ninety-five pounds. She has adhered mainly to this diet, and is now much better and has regained her normal weight. I found, however, that her pulse was 114, and so put her on intestinal antiseptics.

CASE VIII.—Miss C., aged thirty-five years. This case is interesting from the fact that I treated her for epilepsy in 1881, the attacks then having an average frequency of twice a month for seven years previously. Her family (all brothers) are highly neurotic and sufferers from gastric dyspepsia without inflammatory symptoms, one of them also so affected with right-handed tremor that he can not sign checks. After entire freedom from epilepsy for fifteen years, she first consulted me April 23, 1894, with a story of a year's affection of palpitation and rapid heart action, accompanied with a sense of great prostration and muscular weakness, often being suddenly awakened in the night with violent throbbing. Muscular tremor well marked, especially in the hands. Pulse, 116; no cardiac murmur; no exophthalmia, but some slight enlargement of the thyroid. Diagnosis: incipient Graves's disease, and treatment prescribed accordingly.

May 7th.—On the whole better, but has now a tendency to diarrhoea. Whenever this begins her heart is at once affected. Throughout June these bowel attacks would occasionally recur and each time be accompanied with palpitation and nervousness. One of these attacks in July much alarmed her, as threatening a return of her old epilepsy, for she had an attack of blindness come on with numbness of the left side of the nose, tongue, and left arm. Average pulse, 100 to 110. During the rest of the summer of 1894 these irregular attacks of fainting sensations, sometimes accompanied with tenesmus without diarrhoea, continued, but she gradually improved, the pulse slowly falling till last record, February 5, 1896, when it stood at 78, the patient then feeling quite well. The connection between overaction of the heart and intestinal derangement is particularly noticeable in this case.

That migrainous and, in some cases, epileptic attacks also are dependent upon absorption of intestinal ptomaines has long been my belief, and has led to measures of treatment which have seemed to me to be very advantageous. Previous liability to migraine has also been noted more often in the histories of patients with Graves's disease, in my experience, than any one other antecedent.

CASE IX.—Annie H., aged eighteen years, delicate girl, looking quite anæmic. Applied for treatment May 23, 1895. Had lately been losing flesh and was much troubled with her loss of hair. Very nervous and weak, and inclined to frequent attacks of syncope. Pulse, 124.

June 3d.—Felt better and stronger, and had had only one "faint spell" since beginning treatment a week ago. Pulse, 126.

17th.—Better; pulse, 104.

July 8th.—Feeling much improved. Pulse, 100. Though this patient had neither exophthalmia nor goitre when she came on May 23d, during the past week the thyroid enlarged so for four days that she could not fasten her collar around it, but in a few days it again wholly subsided. By September 1st her condition was so good that she ceased attendance, having gained in flesh and color. Pulse, normal, 80.

CASE X.—Miss B., first consulted me February 8, 1894, for daily severe headaches with pain in the eyes, always worse in the morning upon waking, suggesting, therefore, that use of the eyes did not cause, or, at least, aggravate the headaches. She was gradually relieved of the headaches by intestinal antiseptics. She stated that her mother, a maternal aunt, and her maternal grandfather were "martyrs to rheumatism." This patient ceased taking remedies and attendance until, finding the pains in the eyes return, she consulted Dr. Karl Koller of this city, who, April 7, 1896, sent her to me with a note suggesting that she had incipient Graves's disease. I found the pulse 136. She ascribed her relapse to mental causes. Upon putting her upon the treatment for Graves's disease the notes are:

April 25th.—Much improved, but has had an attack of diarrhoea.

May 22d.—Pulse, 96; feels weak, but general symptoms better; headaches less frequent, and sleep much improved.

CASE XI.—Mrs. B., aged fifty-five years, from Massachusetts, March 13, 1895. About three years ago she noticed that her thyroid began to enlarge. This has varied from time to time ever since. Before this came on, according to her statement, she had chronic diarrhoea for four years. Has never had noticeable exophthalmia. She ascribes her trouble to prolonged domestic worry. She is extremely nervous; very weak and tremulous in her voice; weakness of knees much complained of; great tremor of the hands, especially on waking in the morning, as in Case II. Has been steadily emaciating. Pulse, 126; no cardiac murmur. She returned home with directions for treatment, but I received no report from her till June 8, 1896, when she wrote that she was much improved. The goitre still persists, but she considered herself as steadily gaining.

CASE XII.—This case may readily be disputed as one of Graves's disease at all, but when the totality of the symptoms is taken into account, with finally the test of treatment, I am inclined to so regard it. Mr. A. B. S., a lawyer, aged forty-two years; applied first October 28, 1895; light complexion; fairly well nourished; never had syphilis or gonorrhoea. In May, 1894, without any antecedent symptoms of the kind, he was suddenly taken with nausea and gastric distress, which have continued ever since in spite of treatment by a number of our eminent city physicians. His symptoms are an almost continuous nausea, with an ill-defined sense of distress referred to the stomach; no aching or heavy pain radiating anywhere; not made worse by eat-

ing or when the stomach is empty, except that he always feels worse on waking in the morning; tongue always coated deep brown. He can lie as well on either side; no symptoms of gastritis or of tumor on palpation; has had his stomach frequently washed out without any mucus being brought away; no movable kidney; knee-jerks normal, no ataxia or shooting pains. He has been all along sensible of a diarrhoeal sensation in the bowels after movements, even when they seemed to be normal; but, on the other hand, he frequently suffers from apparently causeless diarrhoea. The cardiac feature of his case is that his pulse on his first visit was 130, and during the subsequent twenty-three visits, entered in my note-book till July 2, 1896, it has steadily kept between 94, the lowest, to 140. His other symptoms have been a singular sense of weakness in his arms and legs, but not in the back, with tingling and numbness in both extremities. These symptoms sometimes seem to take the place of his gastric troubles. They are also sometimes accompanied by a sense of fear. Always feels better in the afternoon. His chief complaint, however, is that every few days he feels so prostrated by his various feelings that he can not apply himself to business from his sense of general weakness, both physical and mental. This patient, as stated, had been treated already most perseveringly for his dyspeptic symptoms by others, and for three months I prescribed for his gastro-intestinal complaints as best I knew how, without better success than my predecessors. The continued frequency of his pulse, however, with a normal temperature, without any renal trouble, no cardiac murmur or arrhythmia, and no inflammatory symptoms present in any organ, led me, finally, on February 7, 1896, to put him on the treatment for Graves's disease, although he presented no other symptoms of that complaint, except his anomalous sensations, his feeling of weakness, and his tachycardia. His eyes are somewhat prominent, but not unduly so. From the above date he reported February 14th, March 6th, March 14th, April 20th, May 5th, June 2d, July 2d, a steady improvement. No more trouble with either stomach or bowels. Lately has felt strong enough to ride a bicycle. Pulse, however, at last date, 126.

I have other cases to report when a sufficient lapse of time allows the effects of treatment to be properly tested. This disease runs such a varying course in different patients that it is very desirable that their subsequent history should be obtained as far as practicable. Thus six of the eight patients whose histories are given in my former article in 1893 are still free from a return of their former symptoms, except the fourth in the list, who is yet not wholly well, and shows considerable exophthalmia. She, however, has not been under my care in the interval.

#### ÆTIOLOGY OF DEVIATIONS, SPURS, AND RIDGES OF THE NASAL SÆPTUM.\*

By JOHN O. ROE, M. D.,  
ROCHESTER, N. Y.

It is with considerable hesitation that I present for your consideration some thoughts upon the ætiology of

deviations, spurs, and ridges of the nasal sæptum, especially since the subject has been so ably, clearly, and fully discussed by different members of this association on several different occasions. After considerable study of the subject, however, I have concluded that some points have been overlooked which it is necessary to consider in order to explain why deviations of the sæptum are so frequent in their occurrence, and often so exceedingly peculiar as regards their form, extent, and location.

Deflections of the nasal sæptum are ascribed to a variety of different causes. These may be divided into predisposing and exciting causes.

I. **PREDISPOSING CAUSES.**—The two main predisposing causes are diathesis and racial characteristics.

1. *Diathesis.*—That diathesis is an important predisposing cause of deviations of the sæptum may almost be said to be self-evident, since it is a fact of clinical observation, verified by nearly all observers, that deflections of the nasal sæptum are exceedingly common among persons suffering from the strumous, syphilitic, tubercular, or rachitic diathesis. Loewy\* and Loewenberg† have emphasized the influence of rickets as a predisposing cause, perhaps laying more stress upon this factor than any other authors; and Harrison Allen‡ calls attention to the influence of cretinism in the production of deformities of the nasal chambers.

2. *Racial Characteristics.*—The part that racial characteristics play in the production of deviated septa is an exceedingly interesting topic of study. All writers on this subject are unanimous in showing that deviations of the sæptum are vastly more frequent among the civilized than among the savage races. For instance, among the Europeans and Americans the percentage varies from sixty to eighty per cent., while among the Mongolians, the Africans, and the Polynesians the deviation is found in but about twenty per cent. The increase in frequency of deviation of the sæptum among the civilized, and particularly among the Europeans and Americans, is ascribed to two causes: First, to the increase in the cranial development and the enlargement of the facial angle; and, second, to the admixture of the different races.

Ecker and Lissauer\* have demonstrated that under the influence of an increased development of the cranial mass the schematic line formed by the cranial vertebræ has a tendency to curve in proportion as we advance in the evolutionary transformation. The sæptum, accordingly, describes a movement of rotation, from above downward, from backward forward, around the body of the sphenoid taken as a centre.

Thus it will readily be seen that as this process of

\* *Berliner klinische Wochenschrift*, 1886, No. 47.

† *Zeitschrift für Ohrenheilkunde*, Wiesbaden, 1883, Bd. xiii, S. 11.

\* *Annales des malades de l'oreille et du larynx*, 1892, tome xviii, p. 782.

\* Read before the American Laryngological Association at its eighteenth annual congress.

rotation takes place, the angle formed between the frontal, the superior maxillary, and the sphenoid bones for the accommodation of the sæptum becomes proportionately greater, and as the posterior portion of this angle widens, the anterior portion becomes correspondingly narrowed, which gives less room for the sæptum, particularly the anterior portion. This would account for the seeming redundancy of the sæptum in many cases, there being apparently insufficient room for its accommodation, requiring it to become more or less incurvated or wrinkled, especially the cartilaginous portion.

These studies have been further pursued by Potiquet,\* whose researches were conducted on four hundred skulls in the museum in Paris, from which he shows that the nasal sæptum is more prone to lateral curvature as the angle of the face is more inflected in its antero-posterior direction, and that this angle is more and more inflected in an ascending series as we rise from the anthropoid to the European male.

The cause of the rarity of deflections of the sæptum among the less civilized races is believed to be due to the purity of these races. Among the purer races the features of the people are so much alike that it is with the utmost difficulty that a skilled physiognomist is enabled to distinguish between individuals without a close acquaintance with them. And thus we find that among the Mongolians, the Malays, the Arabs, the Africans, the Polynesians, and the American Indians the shape of the sæptum and the interior of the nose vary as little as does the external appearance of the nose.

Further studies in this direction show that an increase in the frequency of deviations of the sæptum corresponds very closely with the degree of admixture of the different races. This admixture in the more civilized countries, occurring largely as the result of conquest and of immigration, has been taking place from the earliest times, until modern Europe and America of to-day represent this admixture of the races in the highest degree.

The evolutionary changes that have taken place by this admixture are also readily seen in heterogeneity of the features of our people, as will be observed from the fact that no two persons will be found in whom all the features very closely resemble one another. Therefore, as Potiquet observes, "it would not be extravagant to say that a man has only exceptionally the sæptum which belongs to him."

Martin † observes that these anomalies all seem to be more clearly explained by the blending of different racial types than by evolutionary or devolutionary changes from a prognathous to an orthognathous type.

Delavan,‡ in his most instructive article on the *Étiol-*

ogy of Deflections of the Nasal Sæptum, also emphasizes the greater prevalence of deviated septa among the civilized than among savage races, and also points out the fact that the aquiline type of nose, as illustrated in the Slav, the Hebrew, and the ancient Roman,\* is particularly apt to be associated with deflections. A notable exception to this observation is the fact that the North American Indian, while possessing an aquiline nose, rarely has deflection of the sæptum. This is to be explained by the fact that the Indian belongs to a primitive and pure race, and also by their higher physical development on account of their outdoor life, and, as has been pointed out by Catlin,† by the habit among the Indian mothers of closing the mouths of their children and compelling them to breathe entirely through their noses from their earliest infancy, which conduces to a proper development of the nose.

II. EXCITING CAUSES.—The exciting causes of sæptal deflection may be either internal or external.

1. As internal exciting causes we have (a) defective development, (b) diseases of the sæptum, and (c) diseases of other portions of the nose.

(a) *Defective Development.*—In studying deflections of the osseous and cartilaginous sæptum, it is important to call attention to some points in the anatomy of the sæptum. It will be remembered that the nasal sæptum is composed practically of two bones, the perpendicular plate of the ethmoid and the vomer; and one cartilage, the triangular cartilage of the nose. The perpendicular plate of the ethmoid bone is a thin flattened lamella, which descends from the under surface of the cribriform plate, or the horizontal portion of the ethmoid bone, forming part of the anterior fossa of the base of the skull. The lower border of the posterior half articulates with the vomer. The vomer is a single bone situated vertically at the back part of the nasal fossæ. At an early period it consists of two laminæ separated by a very considerable interval, and inclosing between them a plate of cartilage which is prolonged forward to form the remainder or cartilaginous portion of the sæptum. Ossification commences in the vomer at about the same period as in the vertebræ (about the sixth or eighth week of foetal life), but is not complete until after puberty; and the perpendicular plate does not begin to ossify until about the first year after birth. The coalescence of the laminæ takes place from behind forward, beginning about the third year. The cartilage of the sæptum, extending forward from between the two plates of the vomer, is somewhat triangular in form, thicker at its margins than at its centre, and completes the separation between the

\* *Étude critique sur l'étiologie des déviations de la cloison nasale* *Méd. moderne*, Paris, 1892, tome iii, p. 153.

† *Journal of the American Medical Association*, 1894, vol. xxiii, p. 491.

‡ *Transactions of the American Laryngological Association*, 1888, vol. ix, p. 202.

\* In the anthropological collection of the Peabody Museum, at Cambridge, Mass., is a cabinet containing eighteen well-preserved specimens of skulls taken from ancient Roman tombs. Delavan found that among these there was hardly a single instance in which the sæptum was straight, while in several of them the degree of deflection was excessive, and far beyond that usually seen.—*Ibid. cit.*, p. 205.

† *The Breath of Life*, Reprint, New York, 1872, p. 16.

nasal fossæ in front. Bearing in mind this fact that the vomer is composed of two parallel laminae which do not fully coalesce until after puberty—and in some instances do not coalesce at all\*—we can most readily see the effect that would be occasioned by the slightest imperfect development of either of these plates. Hypernutrition of one lamina would cause the other lamina to be pushed out of its normal line of growth; and, conversely, any lack of full development of one lamina would occasion corresponding deviation. Any such deflection in the vomer would naturally be accentuated in the cartilage of the sæptum. The probability of this view that the deflections result from defective development of the plates of the vomer is increased when we take into account the fact that scarcely if ever do we find two bones with precisely the same degree of development.

Morell Mackenzie † evidently alludes to this fact when he says: "It is not impossible that the deflection may result from the fact that ossification of the sæptum proceeds from centres situated in two different bones, and that these deposits of ossific matter do not subsequently meet in the same plane."

The fact that ossification begins in the posterior end of the sæptum and that coalescence takes place from behind forward, explains why that end is rarely observed to be markedly deflected. It is the middle and anterior portions that most commonly become deviated as a result of the abnormal conditions that are so frequently found in children after the third or fourth year. The unequal development of the plates of the vomer and the resulting deflection of the sæptum produced by these abnormal conditions become accentuated as the development of the child takes place. Welcker ‡ has not observed deflections of the sæptum before the fourth year, while Zuckerkandl\* states that he has not observed them in children under seven years of age. Anton, however, has shown that these deviations may be congenital by the examination of fifty-six cadavers of newborn infants, in which he found deviations in nine cases (equal to sixteen per cent.).

The peculiar forms which deflections of the sæptum may assume can readily be explained in the light of the fact that the different plates develop unequally. Unequal development of the separate plates may take place in a vertical direction or in a horizontal direction.

\* In the *Philadelphia Medical News* for January, 1882, Lefferts described a case of double sæptum in a man aged twenty-five. The upper half of the posterior edge of the partition was divided in the vertical direction into two distinct portions, which were separated wide enough to admit the end of a lead pencil between them. The space thus inclosed was triangular in shape, the widest part being above, and the mucous membrane covering it had a natural appearance. Baumgarten, of Budapest, describes a case of a double nose with two cartilaginous septa and three nares.—*Rev. de lar., d'otol., etc.*, 1894, tome xiv, p. 10.

† *Diseases of the Throat and Nose*, 1884, vol. ii, p. 434.

‡ *Die Asymmetrie der Nase und des Nasen-Skelets*, Stuttgart, 1882.

\* *Anatomie der Nasenhöhle*, Bd. i, S. 102, zweite Auflage, 1893.

Thus, if we have a vertical overgrowth of the lamina on one side or a defective growth on the other, we may have simple deflection of the sæptum toward the side of greater development. Again, if we have an overgrowth in one plate in an anterior posterior direction, and of the other plate in a vertical direction, we may have the peculiar conformation of the sæptum called the sigmoid deflection, which naturally suggests the idea of redundancy of sæptal growth, as was first observed by Morgagni.\* Chassaignac † has also advocated this view.

Ingals ‡ has emphasized the importance of local malnutrition as an ætiological factor in sæptal deflection, but, reversing the sequence of cause and effect, maintains that the "deflection of the sæptum usually commences in the cartilaginous portion, and that the flexion of the vomer, which often exists, is of mechanical origin, due to firm articulation of this bone with the cartilage." Others, among whom we may mention Delavan,\* J. N. Mackenzie, † Sedziak, ‡ and Rosenthal, § have, in a general way, considered defective development as an important factor in the production of sæptal deflection.

(b) *Diseases of the Sæptum*.—Hypernutrition of either side in excess of the other may readily be produced by diseases of the sæptum itself. An abnormal condition of the nasal sæptum, which may act as the exciting cause of deviation, is chronic disease of the tissues covering the sæptum, usually associated with more or less disease of other parts of the nasal passages. A condition of hypernutrition of the sæptum may be caused by the engorgement of the cavernous tissues which cover the lower posterior portion of the sæptum as well as the turbinated bodies. This cavernous tissue, as is well known, is so sensitive to irritation as to become readily engorged by any external or internal irritant. Therefore, when this tissue is subjected to frequent irritation, diseased action sooner or later takes place, resulting in chronic distention of the vessels. This hypernutrition tends to an increased growth of the structures, and, as Greville Macdonald † observes, results in a tendency to a vertical as well as a horizontal overgrowth. As, vertically, the sæptum lies between fixed limits, any increase in that direction must result in its being bent to one side or the other.

Supernutrition and a diseased condition of the sæptum may also result in spurs and ridges along the sæptum.

\* *De sed. et caus. morb.*, Lugd. Batav., 1767, epist. xiv, art. 16, vol. i, p. 207.

† *Diseases of the Nose*, London, 1892, p. 195.

These spurs and ridges are usually found located along the articular surfaces of the septum; that is, (1) along the line of junction of the vomer with the superior maxilla, and (2) along the line of junction of the anterior border of the vomer with the triangular cartilage of the septum and the lower posterior part of the perpendicular plate of the ethmoid, and (3) along the line of junction of the anterior border of the ethmoid with the triangular cartilage. The exostoses may be unilateral or bilateral. The ridges along the junctions of the vomer with the triangular cartilage and with the superior maxilla are more often bilateral than the ridges elsewhere. When occurring upon one side of the septum alone, they are frequently looked upon as constituting a deviation of the septum, but they are by no means a condition of deflection. Inflammatory states may not only be excited by a hypernutrition of the part, but may also result from inflammation set up by reason of external influences producing a condition which may be looked upon as an arthritis. These excrescences may indeed be the direct cause of the deflection of the septum, by reason of the pressure which the turbinated bodies may exert upon them, forcing them and the septum over to the opposite side. This condition, however, is not common; for these outgrowths and ridges are usually found upon the projecting or prominent portion of the angle of deflection, and may therefore be looked upon as the result of the condition that has been the primary cause of the deviation.

(c) *Diseases of Other Portions of the Nose.*—Malformation of the superior maxilla and a very small and highly arched hard palate have so frequently been observed to be associated with deflection of the septum as to make it necessary to regard them as an exciting cause. This view was first suggested by Trendelenburg,\* but especial attention was directed to it by Jarvis,† who says that of a number of instances of highly arched palate, in every case deflection of the septum was found. He also states that this condition was hereditary in a number of cases in which he had traced it through several generations.

Welcker‡ has pointed out that a deflected septum is frequently associated with more or less disproportionate development of the whole face. The orbits may lie on different planes, resulting, as a matter of course, in various ocular troubles, and the superior maxilla and alveolar processes may be developed unequally, which may possibly have resulted, as Bosworth§ suggests, from scoliosis of the whole face.

In nearly all cases of deviation of the septum we find the turbinated body on the concave side of the septum very greatly hypertrophied, whereas the turbinated body

on the convex side of the septum may be comparatively small, or at least not in a condition of hypertrophy. An interesting question has arisen in connection with this fact as to which is the cause and which is the effect. Baumgarten\* and some others maintain that the hypertrophy of the turbinated body has been the exciting cause of the deviation, forcing the septum over to the opposite side, whereas others believe that the hypertrophied turbinated body is the result of the septum being deflected from the median line. This latter view is, to my mind, the correct one, for the reason that we usually find the turbinated body on the concave side of the septum sufficiently hypertrophied to fill the space, while not hypertrophied enough to press against the septum. On the convex side, however, we find the septum pressing closely upon the turbinated body. If the deflection of the septum had been the result of the pressure, the pressure found upon the convex side would have been sufficient to force the septum into the median line, or to the opposite side. I believe it is false, however, to hold that the deflection has had nothing to do with the hypertrophy of the turbinated body. The hypernutrition has been caused by the irritation consequent upon the excessive amount of air passing through the unobstructed passage, producing vascularity and hypernutrition of the part. Hypertrophy may be a compensation of Nature for this extra work. It is a well-known fact of observation that when the respired air passes through one nostril only, sooner or later irritation of this nostril is set up. In normal respiration the current of air that passes through the nostrils is equally divided, but when the respiratory current passes through one side only it causes dryness of the passage, irritates the nostril, and there is ultimately more or less diseased action. It is a rule that should be invariably observed that no matter how easily respiration may be carried on through one nostril, the other nostril should be opened so that an equal amount of air may pass through it, although it may not be necessary to make the passage as wide or free as the other nostril, which may be abnormally large. It is almost invariably the case that we find the most disease in the nostril through which the greater current of air passes, and very frequently we see an aggravated form of so-called nasal catarrh in the free nostril very rapidly become ameliorated by establishing free respiration through the other side.

The obstruction of the anterior portion of the nasal passage when the other portion of the passage remains free is undoubtedly sometimes the cause of deviations of the septum, although not the main cause, as it is believed to be by Collier.† The direct effect of obstruction of the anterior portion of the nasal passage during respiration is to cause more or less rarefaction of the

\* Cited by Schaus, *Archiv für klin. Chirurgie*, Bd. xxxv, Heft 1, 1887.

† *Medical Record*, vol. xxvii, p. 284.

† *Journal of Laryngology and Rhinology*, vol. v, 1891, p. 501.

air in that nasal chamber, which, acting upon the normally thin and easily yielding septum, particularly in children, will cause a bending of the septum toward the nasal chamber in which the air becomes rarefied, or, in other words, in which the normal atmospheric pressure is reduced by the inspiratory current. The effect of obstruction of the nostrils in the production of deformities of the face is very clearly shown by Ziem\* in his experiments of artificially blocking one nostril in young animals. In every case there was defective development of the side of the face and skull on the side of the obstructed nostril.

Obstruction of the anterior portion of the nasal chamber may be caused by temporary excessive vascularity and turgescence of the turbinated tissue of the anterior portion of the turbinated body, or by a chronic condition of turgescence and hypertrophy of this tissue. Or the obstruction may be the result of foreign growths, or from synechia, the result of previous ulceration. It may also be due to dislocation of the triangular cartilage, occluding the nostril. A flattened condition of the ala of the nose may also occlude the nostril. Such flattened condition may be due either to the destruction of the shield cartilage of the ala, or to a condition of paralysis of the dilator muscles of the nostril. This latter point has been emphasized by Collier.†

2. *External Exciting Causes.*—The main external exciting cause of deviation of the septum, particularly of the anterior portion, is traumatism. The vast number of cases of deflection in which a distinct history of trauma can be obtained leaves but little to be desired in the way of proof on this point. Traumatism is considered the main cause of deviation of the nasal septum by Bosworth,‡ Geuzmer,\* Ziem,|| Bresgen,<sup>Δ</sup> Schaeffer,◇ Woakes,† Walsham,‡ Voltolini,‡ Stoker,\*\* Moure,†† Rosenthal,‡‡ and Lennox Browne.\*\*

Traumatism may produce deviation of the septum in a variety of ways. It may result either in direct dislocation of the triangular cartilage at its point of attachment with the perpendicular plate of the ethmoid and the vomer, and at the attachment of the perpendicular plate of the ethmoid with the vomer, or the attachment of the triangular cartilage and the vomer with the superior maxilla. The dislocation may take place singly,

or there may be more or less disturbance or dislocation of all these attachments at the same time, should the external forces be sufficient. These dislocations are more apt to take place in children than in adults, owing to the incompleteness of the attachments during childhood. The dislocation, however, may be slight in the child at first, but as the growth of the septum proceeds, the deflection becomes correspondingly accentuated.

Dislocation of the triangular cartilage is, however, one of the most frequent deformities of the septum as a result of traumatism, owing to the frequency of slight blows upon the nose that are not of sufficient force to cause disturbance of the attachment of the perpendicular plate of the ethmoid with the vomer, and also owing to the fact that the triangular cartilage is much the thinnest portion of the septum, and is most easily disturbed by external causes. In many cases there may be no history of traumatism, since the deflection may have resulted from an accident that has long since been entirely forgotten, but which was, nevertheless, the primary cause, as can be readily seen from the overlapping of the parts, which could not easily have resulted from any other cause. The probability that these deviations result from traumatism, though there may be no history of such accident, is heightened by the fact that these cases are found three or four times more frequently in boys than in girls, and in men than in women, the masculine sex being more exposed to injuries of the nose than the feminine. In such cases of deviation, one of the best proofs that the deflection is the result of traumatism is the fact that we almost invariably find a great amount of callus thrown out on the convex side of the angle of the two articulated surfaces, whereas if the ridge had been thrown out as the result of disease of the articulated surfaces, it would be unilateral.

Among other external influences which are believed to be the cause of deviation, habitually blowing the nose with the same hand has been mentioned by Morell Mackenzie.\* A diseased condition of the interior of one nostril, producing a hypersecretion from that nostril, and a person habitually closing the opposite nostril by pressure with the thumb or finger in order to clear the passage of the discharge, and the habit of inserting the finger into one nostril to remove scabs, crusts, etc., would also have a like effect. This does not of itself seem a sufficient cause for the production of a deformity, although it is quite probable that deflection of the end of the nose quite frequently results from this cause, since misshaped noses in the young may be molded into symmetrical form, as was the custom of the ancient Persians with babes of the royal blood, for no man was allowed to sit upon the throne who had a crooked or deformed nose.†

which take place in the composite races in the development of the osseous structures, and particularly those of the face and skull, it is not surprising that these variations should occur quite as frequently in the nasal septum as in other parts. One can not be more forcibly impressed by the frequency of these variations than by examining the various cavities contained within the skull, and particularly the accessory sinuses of the nose. In the examination of any number of skulls no two cavities in the same or in different skulls will be found to be of exactly the same shape, size, and dimensions. Therefore, the great variations that take place in the size and shape of the nasal cavities and the septum can not be wondered at.

From the present status of our knowledge regarding the ætiology of deflections of the nasal septum we may draw the following conclusions:

1. That deviations of the septum are produced by a variety of causes operating upon different persons; and that upon the same person several different influences may be operating at the same time.

2. That heredity plays a very important part as a predisposing cause, not only by the dyscrasias which may be transmitted, but by the blending of different races in the composite type, which brings about an infinite variation in the conformation of the osseous and cartilaginous structures.

3. That the three local causes most frequently producing deviation, spurs, and ridges of the septum are trauma, nasal obstruction, and unequal growth of the different component parts of the vomer. The last-mentioned cause is itself produced mainly by local malnutrition or diseased conditions of the structures of the nasal passages, inducing an unequal development of the two sides of the septum, which causes a bulging or bending to the side of greatest development. The fact that the vomer is composed of two laminae, separated by a plate of fibro-cartilage which is continued forward to form the triangular cartilage of the nose, readily explains how this unequal development takes place.

## NOTES ON METHYL VIOLET: ITS USES IN MALIGNANT DISEASES.\*

By J. GRIFFITH DAVIS, M.D.

METHYL VIOLET is a product of coal tar, introduced to the profession as a therapeutic agent in the latter half of 1890 on the recommendation of Professor Stilling, of Strassburg, who, in association with Dr. J. Wortman, carried out a series of researches on the antibacterial properties of the aniline dyes. I do not propose to go into a discussion of the other methylenecompounds at this time. I am indebted to Mr. F. W. Fink, of the firm of Lehn & Fink, New York, for the principal

knowledge I have gained of the chemistry of the drug. The methyl violet (C. P.) which I have used was also secured from this firm.

This remedy seems to be a mixture of two or more compounds, classed as methyl violets. In 1890 it was copyrighted under the name of pyoctanin. One half to four parts in ten thousand was recommended in general surgery.

Early in the history of these compounds reports were made which were conflicting, some being for and some against them. Under the head of pyoctanin, the products are variable and confusing. I find many persons who speak of pyoctanin *blue* and pyoctanin *violet* as though they were the same, while they are widely different. Hence the necessity for the use of a definite compound from the same group—"methyl violet," specially prepared for medicinal use under that designation (Lehn & Fink, New York).

I have found the literature on the subject meagre indeed. (Through the kindness of Mr. Fink, I received a few statements which had been translated from the German.) Therefore it is quite probable that notes on the subject, with reports of cases, at this time, will prove not alone interesting but useful to those who have not had the opportunity to study the merits of this valuable preparation.

My first knowledge of the drug was through Dr. Elizabeth Snyder, of the Woman's Hospital, Philadelphia. She spoke enthusiastically of its action on pus in an ophthalmic case which she treated in her clinic.

At that time (1891) I was connected with a clinic in Brooklyn. I secured a supply of the drug and prepared a fifteen-per-cent. solution and resolved to use it in the first suitable case that presented itself. As I had no precedent to follow, I felt that I must proceed slowly and carefully.

The first case that came with pus as a prominent factor was that of a little mulatto girl about nine years of age. She had the worst pair of inflamed eyes that I ever saw. Pus was oozing from the corners of the eyes. She was very anæmic and exceedingly nervous. Her eyes were swollen and completely shut (she had to be led into the room); she had a marked strumous diathesis; also had sores on the scalp; she could not voluntarily open the eyes. When I asked her to look at me, she took her fingers to lift the lids and peered at me as though looking from under a cover. The whole conjunctiva was very highly inflamed and congested. I truly felt incompetent to cope with such a case. The child's history was a very sad one. She had been afflicted for two years, being unable to attend school.

They had visited specialists while they had means; then a round of charitable institutions, until, as the mother said, they were completely discouraged. Their poverty precluding the trial of other specialists, I determined to do all I could for the child.

The presence of so much pus at once suggested to my mind the methyl violet. My recollection of its use was a five-per-cent. solution. I reduced my fifteen-per-cent. solution to five per cent. and dropped one drop of this in each eye. The child screamed, the treatment

\* Read before the Alumnae Association of the Woman's Medical College of Pennsylvania, May 8, 1896.

seemed so severe. But I thought she was more frightened than hurt, and insisted upon this being repeated night and morning for one week. I also directed hygienic and dietetic measures as well. Stated as briefly as possible, the additional treatment consisted in administering an alternative tonic made up in the drug department of the dispensary. I do not now recall the exact formula, but made it to meet the indications in the case. Bottle baths were ordered on alternate nights, the sweating process to last thirty minutes. She was then bathed in hot water with ammonia in it, so that the sebaceous material would be softened and all the effete matter removed from the pores of the skin, thus restoring its normal function. On the principle taught in my college days—*i. e.*, "All *débris* thus removed was so much vital force conserved to the internal organs" (the skin doing vicarious work for the heart, the lungs, and the kidneys)—I asked the child's mother to rub her vigorously but lightly to restore an equilibrium to the circulation; then to oil her from head to foot, using all she could absorb. I also prescribed an eye wash to soothe the eyes after the methyl violet had done its work. It was as follows:

R Boric acid,	} each.....	1 drachm :
Sodium chloride,		
Boiling water.....		1 pint;
Tincture of camphor.....		1 drachm.

M. Filter and use freely, allowing the compress of clean linen to remain on the eyes during sleep.

I instructed the mother, an unusually intelligent colored woman, to keep up this line of treatment for a week. The following Monday (one week later) she presented herself at the clinic. I shall never forget my surprise. Such a complete metamorphosis had taken place I could scarcely be made to believe that it was the same girl. All the swelling and inflammation had disappeared. She looked out of her eyes as well as any child. The mother said "it was like a miracle," as any one who saw the case would say. I ordered the drops continued once a day for another week, for fear there might be pus cells in embryo lurking about. Constitutional treatment was also continued for months (I think iodide of iron was prescribed at that time).

In 1893 the father brought the child to my New York office to let me see her. She never had any return of the trouble, and could attend school constantly.

Case II came to the clinic a few days later—a boy of ten or twelve years, with an abscess of the axilla, extending out on the chest. One of the surgeons operated, evacuating a large amount of pus. I suggested washing out the cavity with a two-per-cent. solution of methyl violet to destroy the pyogenic membrane. This was done. The boy, although a very strumous individual, made a very prompt recovery. He was given constitutional treatment also. Having achieved such gratifying results in these cases, I grew enthusiastic over the remedy and used it wherever pus was present.

Case III was that of a woman with malignant disease of the uterus. This case is taken from my books. The previous ones had to be reported from memory, as the record is inaccessible at this time. Mrs. J. M. F., aged sixty-three years; good family history; had borne several children; attributed the cause of her trouble to the birth of a large child, when an extensive laceration of the cervix occurred. It was never repaired. In April, 1892, her daughter appealed to me in the most impassioned manner to do something to ease her mother and prolong her life. For several years she had been

treated in different private hospitals. During this period of masterful inactivity, according to my mind, the golden opportunity of a radical operation was lost.

Later the woman was in Dr. W. Gill Wylie's hospital. He frankly told her the treatment could only be palliative, as the disease had progressed too far for operative interference. He curetted and removed a large amount of pus and *débris*. This arrested the ravages of the disease for a short time. In April, 1892, her daughter who was a patient of mine, brought her to me. As soon as I examined her I felt that there was little hope. I advised the hospital, thinking that with later knowledge and improved technic and devices a hysterectomy might be performed that would prolong her life. The family was desirous of anything that promised relief, so I had a consultation with Dr. H. Marion-Sims. He agreed with me in diagnosis, but with Dr. Wylie in prognosis, that only temporary relief could be given. The patient entered St. Elizabeth's Hospital in May, 1892. Dr. Sims also curetted and removed a large amount of pus and *débris*. He told her husband he did not see how she could live beyond a few weeks.

The woman remained in the hospital about a fortnight. She grew gradually worse after her return home. But her relatives again appealed to me to do something for her. On July 26, 1892 (two months after Dr. Sims operated), I began to give her regular treatment. The case was a desperate one. I only hoped to do what I could to alleviate her sufferings and aid her to die easily. So I began to treat her three times a week; had her douched night and morning with the peroxide of hydrogen solution (forty per cent.). The exudation or secretion from the carcinoma, flowing over the mucous surfaces, was very irritating. It seemed to eat like fire. In this case I began at once with a fifteen-per-cent. solution in ninety-five per cent. alcohol. Cleansing the sores, and then painting them with the freshly prepared solution (it smarted severely) till the spirits evaporated, I followed this with flexible colloidion, which had twenty-five per cent. of castor oil added to the usual formula, as this left a softer surface. This was followed with a covering of compound stearate of zinc, with ichthyol (as prepared by McKesson & Robbins); I used it with an insufflator. This was for its mechanical action, to prevent the moisture of the secretions from acting on the basic treatment. As I was working in the dark, so to speak, I had to formulate my methods to meet the indications in each case as they arose.

In this particular case I felt that I was not reaching the disease where it was doing its worst work—*i. e.*, in the endometrium. I went to a druggist and ordered some soft gelatin suppositories (three grains each)—"pyoctanin violet." I inserted one with curved forceps in one cornu, as nearly as I could imagine, of the uterus at one *séance* and in the corresponding cornu of the opposite side at the next one. I did the best I could in this blind fashion. The patient soon began to manifest great improvement. Pain began to subside very promptly. In less than three months there was a decided amelioration of symptoms—no pus, no pain, no odor. The treatment became routine—twice in a week. Her general health improved so much that she could go out to walk, went to places of amusement, and enjoyed her family. The disease seemed in abeyance for the time being. The woman took new hope and courage. It was not until April, 1893, that the disease began to show progress again, and then only in a general malaise and want of appetite. In May following I found

that the upper portion of the bladder was invaded, producing a vesico-vaginal fistula. In the erect posture she suffered no inconvenience; in the recumbent, urine constantly leaked away. She was naturally a very neat woman, and this manifestation distressed her exceedingly and wore upon her nervous system. In the first part of June she failed rapidly. She complained only of uneasiness. She died very peacefully on June 18, 1893, living about eleven months after I began the use of the methyl violet. Throughout there was never a return of pus, pain, or odor. One of the nurses who attended this case said she would not believe it was a malignant disease, were it not that so many physicians had pronounced it such.

My success in the instance cited above made me anxious to try it on a case where I could reach every part of the growth. I expressed a wish to that effect to several of my acquaintances.

Mrs. C., an old friend and patient living in Brooklyn, knew a mulatto woman who worked for her occasionally. She noticed that the woman was failing in health and made inquiries as to the cause. She told Mrs. C. that she was about to enter the hospital for a second operation upon her left breast. Mrs. C., knowing how much I wanted such a case, promptly suggested that she come to New York and give me at least three weeks' trial. She acceded to the proposition.

CASE IV.—The case presents the following history: M. H., aged twenty-seven years, unmarried; menstruated at fifteen years of age; the flow regular and profuse; no early history of leucorrhœa, although it exists now; has a marked strumous diathesis. At eighteen years of age a small tumor developed above the nipple of the left mammary gland. It grew slowly until she was twenty-one years old. It was removed by a well-known surgeon of Brooklyn. At that time it was considered non-malignant. It remained well for five years. Then the patient began to feel pain and itching at the lower portion of the cicatrix, corresponding to the place where it originally began growing. A small pimple made its appearance. Some one advised a domestic remedy—a poultice of plantain leaves—which she used. A patch of white pimples, as she described them, resulted. They became confluent and formed a crust. The pain was not so great as a peculiar itching and stinging, which was constant. It began to spread; it was raised and indurated. She consulted physicians and underwent all manner of treatment. The sore utterly refused to heal. Operative measures were advised and urged, as it was rapidly approaching the axilla.

The present appearance and history suggested the squamous variety of epithelial carcinoma. The patient said she would be insane if she did not soon get relief; could not sleep day or night. The only relief she had was to take a piece of coarse muslin and rub the sore with it. She remarked that by this process she peeled off a handful of stuff that looked like dandruff. I began with a fifteen-per-cent. solution of methyl violet in ninety-five per cent. alcohol; used a soft brush and painted in every nook and crevice of the growth with this freshly prepared solution; followed it with flexible collodion, as in the previous case. The wound was then dressed with marine lint covered with absorbent cotton. The woman was instructed not to touch it until the

night previous to coming to me again (four days later). I also gave her an alterative tonic, as follows:

R Scherf's syrup of hydriodic acid.... 3 ounces;  
Compound syrup of manganese.... 4 "  
Elixir of iodobromide of calcium.... 1 ounce.

Mix. Sig.: A teaspoonful in a wineglassful of water an hour and a half after meals.

Chronic constipation was a marked symptom in this case. For this condition I ordered compound licorice powder, a teaspoonful on retiring, or enough to secure one full evacuation of the bowels each day. The patient had worked very hard up to May, 1893, but has not been able to do much since (now January, 1894). To cleanse the sore, I ordered it sponged gently with very hot water containing lysol, a drachm to the pint. This was always done on the night previous to her visit to my office. It is not necessary to enter into the details of each day's treatment. The above-named course was followed closely until March 6, 1894, when the most remarkable result yet occurred. The night before, when she removed the dressing, the whole mass came with it, leaving a clean surface, with here and there a sulcus, where it had eaten in deeper. It gave the impression of a jelly mold. There was still slight itching where it started, although the woman said she felt better than for many months previous. She still continues the treatment with methyl violet (ten per cent.). On March 20, 1894, I began to treat the patient once a week; advised her to keep up the alterative tonic for at least one year. The skin grows more nearly normal at each visit. She was now growing anxious to return to work. On April 27, 1894, I discharged the case, asking her to return at once should she have any of the old symptoms—and to return, anyhow, in one year to let me see her condition, which she did in April, 1895. I have heard recently, through the lady who sent her, that she still remains well.

It is nearly five years since I began the use of this drug, and have always met with success. One must exercise judgment as to the strength of the solution and its preparation, which must be in small quantities, kept well corked and in the dark.

CASE V.—Mr. J. H. V. B., aged fifty-six years; occupation, farmer; never very robust. When about twenty years of age he noticed a small white pimple or growth on his right cheek, near the angle of the nose. It grew very slowly until he was fifty-four years old. It was then struck with a piece of wood. From that time on, it grew rapidly; felt sore, with shooting, stinging pains. His general health began to fail, as he could get no sound sleep day or night; it even hurt him to chew his food. He consulted physicians and tried different remedies in every direction, with no abatement of symptoms in any way. The growth was now about an inch and a half in diameter at its base and gave the appearance of a discolored English walnut. When this patient came to me (about July 1, 1895), I told him I had never attempted the removal of a similar growth, but I agreed to do the best I could for him. I began at once with a fifteen-per-cent. solution of methyl violet, with the happy result of relieving the pain, or stinging and itching, within two weeks. The growth presented a smooth, hard surface. I covered it with flexible collodion (the same as in the previous cases). It began to diminish slowly for four months, at the expiration of which time a piece as large as a hazelnut dropped out. Two weeks later, another similar piece fell out, and about two weeks after this I tied off the remaining piece, disclos-

ing the feeder, a large artery. It bled profusely. When I got the hæmorrhage stopped I went right on treating the base, following this with flexible collodion; also had him use alternative treatment, both vegetable and mineral, alternating. Notwithstanding my inability to see him for weeks at a time, he kept on improving steadily. At this writing (April 16, 1896), he reports himself in better health than ever before. I have kept him supplied with small quantities of methyl violet (ten-per-cent. solution) to apply at home once a day. After the removal of the pieces mentioned above, there was a raised, indurated border, as is usual in such cases. This I treated with a compound of iodine and phenol (one part of the first to two of the last) to hasten the absorption of this tissue. The vegetable alternative was a decoction of burdock root and black alder bark, which the patient gathered on his own farm. The mineral alternative was Parke, Davis, & Co.'s hæmatic hypophosphites (two parts) and Scherf's syrup of hydriodic acid (one part). He takes this an hour and a half after meals, so that the starch in digestion may not interfere with the iodine in the preparation. This combination seems to do good service where there is a strumous diathesis.

CASE VI.—M. D. L., aged sixty-two years, robust and healthy as a young man. His health was impaired while connected with the army in 1862-'63. After his return from the war, he noticed a small black scab, about the size of a pinhead, on his right cheek. He thought possibly it was a grain of powder, and had his wife try to pick it out with a needle. It was situated about an inch below the angle of the eye with the nose, and remained in this condition for over twenty-five years, being scarcely noticeable. About five years ago the wound began to itch and sting; so much so, he could not keep his hands off it. It began to spread. The patient consulted physicians all around the country. He was applying for a pension. The examining board of the Pension Bureau pronounced it malignant; told him the only thing to do was to go to some hospital and have it cut out, with the assurance that he would, in all probability, lose his eye. He shrank from the alternative and let it alone.

The sight of the eye was so much impaired he could not read with it. His health failed. He came to my Keyport office in July, 1895. At that time the inflammation was fully three inches in diameter, involving the eye, a large part of the cheek, and up to the ridge of the nose. In the centre of this area of inflammation was a deep sore, an inch and a half one way and an inch another, with a deep hole in the middle of it. It was a very vicious-looking sore indeed. The conjunctiva was injected and inflamed; it looked like red flannel. So far, he could get nothing to allay the serious symptoms. In his own words, "the more he attempted to put on, the worse it grew." The itching and stinging were unbearable. His appetite being gone, and getting but little sleep, he was thoroughly discouraged. I certainly entered this case with serious misgivings. But I began with a ten-per-cent. solution of methyl violet. The first week the patient said the treatment was like lifting him into a new world, as the pain and itching began to subside at once. He had to come from the country, too, and sometimes several weeks intervened between his visits. He was supplied with fresh solutions from time to time, so he could have it applied once a day. Vegetable and mineral alternatives were also prescribed, as in previous cases, with the same result. On April 16, 1896, all the inflammation, except in the

central sore, had disappeared from the nose, eye, and cheek. It is so much improved that the hole in the centre is filled to the level of the face. The sore could be covered with a silver ten-cent piece. Vision is restored also. There was an elevated, indurated border surrounding it, reminding one of the crater of an extinct volcano. Within two months, by the use of the iodinated phenol, the cicatricial tissue has become very nearly absorbed. The patient says he has better health now than for thirty years previous, having gained about ten pounds in flesh. I am still treating the case, with every prospect of success.

Since the foregoing reports were written, the mulatto woman, who had squamous epithelial carcinoma, made her second annual visit. She reports herself still well, never having had any return of the trouble in her breast since I discharged her in April, 1894.

## HEAT WAVES AND GLARE.

By S. BUSBY ALLEN, M. D.,

ASSISTANT SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL.

In studying the effect of glare upon the eye I have been led to believe that not the light but the heat rays do most harm. A beam of light consists of two distinct kinds of waves—light waves and dark or heat waves. The force of energy of the dark waves in the incandescent light—*e. g.*, electric light or Welsbach light—is seven times that of the light waves. This is a greater proportion than that found in sunlight. All objects in Nature emit these dark waves continually. The ultra-violet, violet, and indigo rays give off very little heat, but from blue to red they steadily increase, and the distance of the line *a*, *b*, *c*, *d* from the line *a*, *b* is the measure of this energy; *e*, *b* is the measure of the hottest

of the visible rays. Pushing the thermo-electric pile toward *d*, the curve bounds up, till at *f* it reaches *c*, and then it falls more rapidly than it ascended. These ultra-red or obscure rays can be focused. We can not see the focus, but it will char itself out of white paper, or it will burn anything that is inflammable; or, focused on a sheet of thin platinum, it will raise it to incandescence, thus changing dark to visible rays.

In Professor Tyndall's famous experiment these rays were focused on the retina, a plate of metal with an aperture of the size of the pupil being used to protect the

surrounding parts from the intolerable heat. Describing this experiment, Professor Tyndall says: "Removing the eye, but permitting the plate of metal to remain, a sheet of platinum foil was placed in the position occupied by the retina a moment before; the platinum became red hot. No sensible damage was done to the eye by the experiment. No impression of light was produced; the optic nerve was not even conscious of heat." It was afterward found by experiments upon the eye of an ox that eighteen per cent. of the rays reached the retina, the rest being absorbed by the aqueous and vitreous. Why did not this intense energy, which raised platinum to a red heat, destroy the cornea at least, supposing the aqueous to be sufficient to protect the rest of the optic tract? The explanation lies in the briefness of the exposure. The cornea was protected by the tears, just the same as the wetted finger is protected when plunged in molten metal and quickly withdrawn. A prolonged exposure would have utterly destroyed the eye. It is this prolonged but less intense exposure that affects the eye in glare. Many persons exposed to glare by the nature of their occupation are obliged to quit work altogether, or to lessen their hours of work; or, more's the pity, to work on and suffer, thereby setting in operation a vicious chain that may possibly end in atrophy of the optic nerve. These patients, even after their errors of refraction, if they have any, have been corrected and their conjunctivitis has been treated, and the irritating light rays, and also many of the heat rays, cut off with tinted glasses, still continue to suffer. In vain the ophthalmologist resorts to tonics. Nothing will suffice save rest or change of occupation.

The Bessemer steel employees, who are exposed to intense glare, wear a huge lens composed of three glasses—the centre a dirty chocolate, sandwiched between a green and a blue; still they suffer intensely from the heat waves.

In an article entitled *Asthenopia due to Glare*, published in the last number of *The Manhattan Eye and Ear Hospital Reports*, I expressed my surprise that the only pathological change found in these cases was "a redness of the disc and retina to the nasal side of the disc." One would naturally look to the layer secreting the visual purple for morbid effects if light waves were the sole or chief cause. If, however, the heat waves play the most important rôle, this is the part of the fundus that would suffer most, as the bridge of the nose would act as an efficient screen to protect, to a great extent, the temporal side. If a beam of light be passed through a glass tube containing pure water, or, what is far better, alum dissolved in water, the heat rays are mostly cut off, while the solution is transparent to light rays. Here, then, I think we have the means to relieve our sufferers from glare. I am having Mr. Georgan, the optician, construct for me glasses containing this solution between two plane surfaces of London smoked. These glasses will not be over bulky or heavy, nor will they

be very expensive, and can be worn not only to relieve those who suffer but also as a prophylactic. It would also be very easy to devise a ground-glass shade with hollow walls containing this solution and place them over the electric lights. A little wider knowledge of irritating and soothing colors would effect changes that would prevent much of the glare from which we now suffer. I spent the heated term at a place most irritating to the eye. A land company had built the roads of oyster shells, which had been ground to a fine white powder. These roads must have reflected over eighty per cent. of the light thrown upon their surfaces. After spending the morning on the roads, the beach, or the water, to enter the dining room was a great relief. The walls and ceilings were done in oil—surfaces rough. The walls, a chocolate-brown, with those uneven surfaces reflected less than ten per cent. of the light thrown upon them. The ceiling, a pale yellow, reflected about forty per cent. The broad blue cornices joining them would absorb all but twenty-five per cent. Guests at the six o'clock meal would call attention to "how short the days have grown!" and call for artificial light. How different are the walls of most of our business places and our homes! The walls' plane surfaces either reflect too much light or, with papers in colors too pronounced, irritate and fatigue the eye. In general terms it may be said that yellow, red, and violet rays irritate, while blue, green, and brown, if not too pronounced, are soothing. Sharp contrasts of light and shade, as too sharply defined shadows when writing or drawing, are very fatiguing. This is why artists love the north lights—the edges of the shadows are not so sharp and the outlines of things are softened.

141 EAST EIGHTY-NINTH STREET.

## MULTIPLE FIBROIDS OF UTERUS, WITH HYDROSALPINX. HYSTERECTOMY BY SEGOND'S METHOD.

BY WILLIAM C. WOOD, M. D.,

GYNECOLOGIST TO NATHAN LITFAUER HOSPITAL, GLOVERSVILLE, N. Y.

Mrs. S., aged forty-one years, married, has had two children; weighs one hundred and sixty-nine pounds, but is very anæmic and weak. Six years ago had a frightful hæmorrhage, and after that flowed too much and too often at her periods. Three years ago thinks she had a miscarriage, and since has flowed almost continuously, getting sometimes less than a week's interval. She has been so bad at times that the vagina had to be tamponed. She says that she had a polypus removed eighteen years ago and was quite well after that until the hæmorrhage of six years since.

Lately she has had severe pains in the lower part of her abdomen, through the ovaries, and in the uterus, and with the constant flowing has become so miserable that she desires an operation.

On examination I found the uterus hypertrophied and very hard, the tubes enlarged and painful, while the cervix had an unpleasant appearance, but there was

no discharge and no odor. My diagnosis was salpingitis and fibroid tumor of the uterus, with a fear that the cervical induration might become in time malignant. I advised a total ablation of the uterus and appendages as the surest and safest method of cure, to which she readily consented, life in her present condition, she said, not being worth living.

Operation on August 10th at Nathan Littauer Hospital. The vagina was first scrubbed with green soap, applied with a sterilized paint brush, and thoroughly irrigated with sterilized water. The cervix was grasped between two traction forceps, one on each lateral half, and strong traction made. With the blunt scissors a circular incision was made around the cervix, and the uterus separated from the bladder by the finger and Douglas's *cul-de-sac* opened. Short-bite forceps were applied to each uterine artery and the cervix cut away from the broad ligament on each side, as high up as the beaks of the forceps went. I then split the cervix with the scissors vertically and removed each half, taking care, of course, to advance my traction forceps so as never to lose my grip on the uterus. This not removing enough of the uterus, in my opinion, to make it rotate easily, the procedure was repeated, and two more portions removed.

Then introducing my scissors so that one blade lay in the uterine cavity and the other in the utero-vesical space, I slowly split the anterior wall, following up the cutting with successive applications of the traction forceps until the fundus was reached, when it rolled easily forward and presented at the vulva. Clamps were then applied to each tube and the uterus cut away.

The right tube was a hydrosalpinx about an inch in diameter; this with the ovary was drawn down and a clamp applied, when the appendages were cut off. The left tube and ovary, both much enlarged, were similarly treated, the wound sponged out, and iodoform gauze packed about the beaks of the forceps and in the vagina. The whole operation, thanks to the excellent help rendered by the *Sécond* patterns of instruments, occupied but twenty minutes.

The examination of the specimen removed showed the presence of a thickened tube and ovary on the left, and a hydrosalpinx on the right side, while the uterus contained a submucous fibroid two inches and a half in diameter, and two smaller fibroids about three fourths of an inch thick, these last being buried in the uterine wall.

The cervix was indurated and ulcerated, having to the eye the appearance of a beginning epithelial growth. The clamps were removed at the end of forty-eight hours, and the patient has since progressed rapidly, and is to-day, twelve days after the operation, sitting up part of the time, with pulse and temperature normal, and having but a slight discharge from the vagina.

**The Buffalo Academy of Medicine.**—At the last regular meeting of the Section in Surgery, on Tuesday evening, the 6th inst., the following papers were read: The Semi-centennial of Anæsthesia, by Dr. Roswell Park; and Anæsthesia as a Factor in Surgical Diseases, by Dr. Woods Hutchinson. Dr. R. R. Ross gave an exhibition of the Röntgen-ray apparatus with demonstrations.

**Syracuse University.**—The new building of the College of Medicine was formally opened on Monday evening, the 5th inst. The chancellor of the university, the Rev. Dr. Day, made the opening remarks, which were followed by a response by the dean, Dr. Henry D. Didama; a history of the building, by Dr. Gaylord P. Clark, of the medical faculty; and an address by Dr. Stephen Smith, of New York.

## A CASE OF CHRONIC PLEURISY WITH EFFUSION TREATED WITH PROTONUCLEIN.

By ALMON H. COOKE, M.D.,

INSTRUCTOR IN MEDICINE  
IN THE MEDICAL DEPARTMENT OF NIAHARA UNIVERSITY, BUFFALO, N. Y.

ON June 2d of this year, a lady came into my office in a greatly disturbed state of mind, telling me that she had suffered from an attack of pleurisy since March 1st, and now she had been told that "it had turned into an abscess on the lung, and that "she must go to the hospital (to her a place of torment) and have a tube put through her ribs," to say nothing of being "laid up" for six or eight weeks.

She was very thin, having lost ten pounds or more, and complained of severe pain at the base of her right lung when she took more than a shallow inspiration. She also said that there was a sensation of fluid running in her chest when she brought it to a horizontal position. Her temperature was 100.5° F., and, to use her own expression, she felt "altogether miserable."

On examination there were evidences of adhesions at the base of the right lung, also indications of a small amount of fluid which I suspected would be pus. However, the exploring needle proved it to be of a serous nature, slightly cloudy, due to the presence of a few pus cells. The following treatment was outlined, and, I am happy to say, was faithfully executed:

Protonuclein tablets, three grains (Reed and Carnrick), half an hour before meals and at bedtime, subsequently increased to five tablets *per diem*. Also ten minims of fluid extract of cascara at bedtime, to regulate the bowels, which were in a torpid condition. Besides this, the surface over the painful area was painted with iodine every second or third evening, as the condition of the skin permitted.

Her diet consisted of not less than half a pound of lean beef or chops at two meals each day, with vegetables in limited quantities, to which was added half a pint of cream each day, to be consumed in a manner most agreeable to the patient.

The result of this treatment was, that the patient gained flesh at the rate of a pound a week and strength in accordance. The temperature became normal at the end of the second week, and deep inspiration gave no pain early in the third week. No trace of fluid could be found by the tenth day, while after eight weeks of treatment the patient declared that she never felt better in her life.

This case seems to me to be one which demonstrates the beneficial properties of protonuclein, especially when combined with a nourishing diet. There can be no doubt that this case would have terminated in empyema, and that very shortly, had active treatment been delayed; and I believe that many cases of pleurisy with an effusion which is not absorbed so rapidly as it ought to be, would be speedily cured by a treatment substantially the same as the one employed in this case.

410 ASHLAND AVENUE.

**Changes of Address.**—Dr. C. Cole Bradley, to No. 51 West Fifth Street, New York; Dr. W. B. Pritchard, to No. 105 West Seventy-third Street, New York.

## TWO INTERESTING NASAL CASES.

BY ELLWOOD MATLACK, M.D.,  
PHILADELPHIA.

1. *Primary Nasal Syphilis*.—Intranasal chancre is, perhaps, sufficiently rare to warrant the report of the following case in some detail:

The patient is a turnkey in a local police station, compelled to come in contact with all the lower classes. He noticed some weeks ago a slight discharge from the right nostril, at times tinged with blood; soon after he began to experience difficulty in breathing through that side.

My first examination showed an ulcer with infiltrated edges, occupying a portion of the anterior end of the inferior turbinated bone, and extending along the inner surface of the ala to within a short distance of the mucocutaneous junction. It was covered with a slough which, together with the infiltration, caused almost complete occlusion of the nostril.

Ordinary stimulant and escharotic treatment proved of no avail, the ulcer enlarging and causing swelling of the submaxillary glands, and a very marked prominence of the external surface of the nose. The ulceration soon became phagedenic, and, fearing external perforation, I placed the patient on full doses of mercury, the effect of which was almost at once perceptible, the ulcer disappearing completely in three or four weeks.

Infection in this case apparently resulted from picking the nose after contact with syphilitic poison from one of the prisoners. In view of the occupation of the patient, the physical characteristics of the ulcer, the marked infiltration, the enlargement of the submaxillary glands, and the result of specific treatment, there can, I think, be no question of the diagnosis, even though I was compelled to use mercury before any cutaneous lesion could appear.

2. *Nasal Cystoma*.—Medical literature contains few references to true cystic growths of the nasal cavities, other than cystic degeneration of myxomata, which probably is not rare.

The cystoma coming under my observation occurred in a lady whom I had treated with considerable regularity for two or three years past, her symptoms being those of obstructive nasal catarrh and marked tinnitus and slight deafness in the left ear. Most of the pathological processes were more marked on the left side and included hypertrophic turbinals and general thickening of the post-nasal structures and crust formation in the pharyngeal vault. These lesions were treated in the usual manner with complete relief.

Some months after the last operative treatment, she began to complain of an intermittent, unilateral nasal discharge, and pain referred chiefly to the left malar bone and lower edge of the orbit, which gradually increased in severity until there appeared the discharge of straw-colored fluid from the affected nostril, when all the symptoms would disappear for a time. Examination revealed a large mass, having the appearance of a myxoma, attached to the posterior end of the left middle turbinated, and extending over and at times covering the pharyngeal opening of the Eustachian tube. Contact with a probe caused the rupture of one of the di-

visions of the cyst, and the escape of a considerable amount of fluid. A snare was slipped over the mass and it was removed, most of the fluid escaping during the operation. It proved, upon examination, to be a multilocular cyst, and in structure showed no relation to ordinary nasal polypi. Immediate relief of all the symptoms followed.

A peculiar feature of this case is that, although the cyst has been removed but three months, and the removal was apparently complete, yet there has been recurrence, and a cyst nearly as large as the original one occupies apparently the same position. The aural tinnitus has returned, but there have been no neuralgic symptoms.

UNION MISSION HOSPITAL, September 12, 1896.

## Therapeutical Notes.

**Atropine in the Treatment of Pharyngeal Diphtheria**.—Elsaesser (*Therapeutische Monatshefte*, August, 1896; *Therapeutische Wochenschrift*, August 23, 1896) employs the following formula:

R Atropine sulphate..... 0.045 grain;  
Cocaine hydrochloride..... 0.75 "  
Bitter-almond water..... 300.00 grains.

M. S.: One drop every hour for each year of the child's age.

For adults, according to the patient's constitution and the severity of the disease, he orders from ten to fifteen drops every hour. The frequency of administration is important, and at first it should be kept up even at night; consequently great care is necessary on the part of the nurse.

**The Treatment of Urticaria**.—The *Glasgow Medical Journal* for September states that Mr. Hutchinson reports, in the July number of the *Archives of Surgery*, the effects of treatment in the case of a lady who had for six months suffered from a peculiar form of tuberosc urticaria. The attacks affected the face and caused much swelling; also the throat, producing such a sense of suffocation that the patient feared she would choke. Arsenic was used without any obvious effect. Then the patient was ordered a mixture containing in each dose two grains of quinine and a drachm of tincture of cinchona, and after this had been continued for four months the liability to the attacks of urticaria had entirely ceased and the patient's general health was much improved. At the end of the quinine treatment, an attack of shingles on the side of the chest occurred.

**Savine in the Treatment of Vegetations of the Vulva**.—Dr. Lataud (cited in the *Journal des praticiens* for September 26th) uses for small vegetations the following formula:

R Powdered savine, } of each..... 25 parts;  
Desiccated alum, }  
Corrosive sublimate..... 1 part.

M.

A more active application is the following:

R Powdered savine, }  
Iodoform, } ..... equal parts.  
Salicylic acid, }

CHELIDONIUM IN THE TREATMENT OF CANCER.

AMONG the many medicinal virtues that have been popularly imputed to the juice of *chelidonium majus* is that of curing warts. Acting on this hint from domestic practice, Dr. Denissenko (*Vratch*, 1896, No. 30; *Deutsche Medizinal-Zeitung*, September 24, 1896) has tested its action on carcinomatous growths in the municipal hospital in Brjansk. In his early experiments he used the fresh juice of the herb, but those trials were imperfect, partly because the patients, being still able to work, would not remain in the hospital more than two or three days, and partly because the fresh juice could be obtained only during two months in the year. Consequently, since February, 1895, he has been using the extract found in the shops.

His method of employing chelidonium is as follows: He directs that from twenty-two to seventy-five grains of the extract shall be taken internally, dissolved in distilled water or peppermint water, every day throughout the treatment. Into the substance of the tumor, as close as possible to the boundary between it and the healthy tissue, he throws a number of injections of from two to four drops of a mixture of equal weights of the extract, glycerin, and distilled water, not exceeding a syringeful in all. The frequency with which these injections are given is not stated. If the tumor is ulcerated, he paints its surface twice a day with a mixture of one or two parts of the extract and one part of glycerin. Iron, quinine, and other supporting remedies are employed according to the indications.

Except in a few cases, the internal use of the drug caused no disturbance of the stomach, but the painting of the ulcerated surfaces gave rise to a slight and transitory burning. It was different with the parenchymatous injections; in all instances, after the injections, especially after the first one, there was burning pain at the site of the operation, the patient felt weak, there was a more or less severe chill, and then the temperature rose to between 100° and 102° F. Although these symptoms disappeared on the following day, Dr. Denissenko saw reason to exercise a certain amount of caution in the use of the injections.

The effects of this treatment were shown in the course of a very few days. They were the following: 1. The sallow hue of the skin disappeared. 2. Softening of the tumor set in. 3. After from three to five days, there formed at the points of injection fistulous tracts about which the softening process went on with special rapidity. 4. In from fifteen to twenty days a line of demarcation could be distinguished between the morbid and the healthy tissues; the one seemed to be forced away from the other. In general, the tumor diminished more than half in circumference, and the affected lymphatic glands of the neighborhood underwent involution.

It is to be hoped that further trials will be made of this simple method of combating so dreadful a disease as cancer, and that it will prove as effective in the hands of others as it seems to have proved in Dr. Denissenko's.

THE INFLUENCE OF EBERTH'S BACILLUS AND THE BACILLUS COLI COMMUNIS ON THE SERUM.

AT a recent meeting of the Lyons Society of the Medical Sciences, a report of which appears in *Lyons médical* for September 20th, M. Rodet stated that in the course of several months he had subjected a sheep to numerous injections of cultures (living or killed by heat) of the bacillus of Eberth, and another sheep to a perfectly parallel treatment with cultures of the *Bacillus coli communis*. The two animals had behaved remarkably alike as regarded their febrile reaction. Although they were as yet but imperfectly protected against the bacilli, their serum already showed in a high degree the curious property insisted upon by Gruber of immobilizing, agglutinating, and precipitating the microbe with which they had respectively been inoculated; it was somewhat the more decided in the serum of the sheep that had been treated with the *Bacillus coli communis*.

In each instance the action of the serum was not limited to the microbe that had furnished the material with which the animal had been inoculated, although upon that organism it was the more pronounced, so that, for example, the *Bacillus coli communis* was almost inert in the presence of serum from the sheep that had had the Eberth-bacillus treatment. Placed in a mixture of equal parts of that serum and bouillon, the colon bacillus did not grow in the form of a homogeneous cloud, but in that of a grumous precipitate, absolutely the same as in a similar mixture of bouillon and serum from the animal treated with its own products. On the other hand, the Eberth bacillus was much more affected by the colon-bacillus serum, although not so energetical-

ly as by the other serum. This action of the colon-bacillus serum on Eberth's bacillus, M. Rodet remarked, was not that of mere serum, for the serum of an uninoculated sheep had no such effect; moreover, neither the colon-bacillus serum nor the Eberth-bacillus serum had any influence on the Löffler bacillus.

M. Rodet had also tested the serum from the two animals with respect to their preventive power. On administering them to guinea-pigs before inoculating them with virulent cultures, he had observed a sufficiently energetic preventive power on the part of the colon-bacillus serum against infection by that bacillus, and on the part of the Eberth-bacillus serum against infection by the *Bacillus typhosus*. Moreover, he had observed that the colon-bacillus serum exerted a preventive action against infection with Eberth's bacillus—slight, to be sure, but very manifest and superior to that exerted by the serum of an uninoculated sheep. Finally, M. Rodet held that his results weakened the force of the argument that had been drawn from the action of the serum of protected animals against the view that the *Bacillus coli communis* and Eberth's bacillus were closely allied; but they did not establish the fact of a radical separation between them.

### MINOR PARAGRAPHS.

#### PROPOSED MEDICAL LEGISLATION IN VERMONT.

A SOMEWHAT hasty examination of the draft of a proposed act to create a State board of medical examiners for Vermont, which reached us too late for insertion in this issue, seems to warrant the provisional conclusion that the bill is a judicious one in the main. One thing in it, however, we do strenuously object to, and that is that it designates non-sectarian physicians as "allopathic." By all means, let this blunder be corrected.

#### ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 6, 1896:

DISEASES.	[Week ending Sept. 29.]		Week ending Oct. 6.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	29	6	35	7
Scarlet fever.....	50	3	48	7
Cerebro-spinal meningitis....	1	1	0	0
Measles.....	36	1	20	6
Diphtheria.....	142	26	169	16
Tuberculosis.....	155	106	158	107

**The National Sanitary Association**, composed of members of various sanitary boards, will hold its annual convention in Brooklyn on October 13th, 14th, and 15th. The officers are: Wallace Sibley, M. D., of Rochester, president; F. O. Young, M. D., of Lexington, Kentucky, vice-president; Thomas E. Veal, of Atlanta, secretary; and C. E. Hoadley, of New Haven, treasurer. The chairmen of committees are as follows: Executive, E. A. Wilson, M. D., of Meriden, Connecticut; laws, C. E. Hoadley, Esq., of New

Haven; contagious diseases, F. A. Jewett, M. D., of Brooklyn; collection and disposition of garbage, Thomas E. Veal, of Atlanta; potable water, F. O. Young, M. D., of Lexington, Kentucky; food, Floyd W. McRae, M. D., of Atlanta; milk, Z. Taylor Emery, M. D., of Brooklyn; plumbing and drainage, Andrew Young, of Chicago; vital statistics, C. E. Hoadley, of New Haven.

The following papers have already been prepared for the convention: Municipal Control of the Consumptive, by Thomas C. Craig, M. D., of the United States Navy; Notes on the Bacterial Diagnosis of Pulmonary Tuberculosis and Mixed Infection, by Charles B. Fitzpatrick, M. D., of the New York department of health; Notes on the Small-pox Epidemic of 1893 and 1894 in Brooklyn, by H. H. Morton, M. D., of the Brooklyn department of health; The Work of the Division of Contagious Diseases of the Health Department of the City of New York, by Charles S. Benedict, M. D.; The Enforcement by Legal Process of Municipal Sanitary Ordinances, by Albert R. Moore, Esq., counsel to the department of health, Brooklyn; Contagious Disease. What is it? Cause, Prevention, and Treatment, by William P. Yonkey, of Lafayette, Indiana; and Scarlet Fever, by J. F. Kennedy, of Des Moines, Iowa. Papers are also expected from Colonel George E. Waring, Jr., commissioner of street cleaning, New York; Professor E. H. Bartley; Dr. E. A. Wilson, of Meriden, Connecticut, and others. Surgeon-General Sternberg, of the army, is expected to be present and discuss a paper.

**The Regulation of Medical Practice in Wisconsin** is in sore need of a radical change, if we may judge by a circular issued by the Wisconsin Eclectic Medical College, of Milwaukee, which was recently received by a New York physician, who has turned it over to us with the question "Can it be possible that any one can secure a diploma and practise medicine for thirty-five dollars and a fake examination?" Among other remarkable things, this precious circular says:

"During the course of our correspondence we often find persons that have been acquiring knowledge of medicine for many years past and some that have practiced medicine successfully for differing periods of time, but are at an immense disadvantage in States where monopoly laws exist. If such a person will please give us a statement of the circumstances, giving time they have studied or practiced or both, we will arrange for their examination at their own home, and if the examiners of this college find it satisfactory they can be legally and lawfully graduated, receiving the diploma of the college, conferring the degree of doctor of medicine without attendance at the college. The examination questions are all asked with one principal object always in view, they are all soundly practical and are intended to show if the applicant is actually in possession of the knowledge and qualifications requisite to become a safe and competent practitioner. Some are already fully qualified to pass the examination, while again others are deficient in some respect and not quite up to our standard, in such cases a diligent study of proper books will soon remedy the trouble and when they are sufficiently qualified, the degree of doctor of medicine, can be conferred at any time. The time of graduation and obtaining a legal medical diploma is a very great event in the life of any person, as the append of M. D. always, raises the individual in the social scale no matter who he or she may be. It also gives to its owner a position . . . which is absolutely unobtainable by any other means."

The illiteracy of the foregoing quotation we have made no attempt to disguise, contenting ourselves with pruning its profusion of capital letters. Can the people of the State of Wisconsin endure the reputation of tolerating such an institution?

**Army Intelligence.**—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 26 to October 3, 1896:

DAVIS, WILLIAM B., Captain and Assistant Surgeon, is granted leave of absence for twenty-five days.  
FAUNTLERROY, POWELL C., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Grant, Arizona, and ordered to Fort Niobrara, Nebraska, for duty.

McCREERY, GEORGE, Captain and Assistant Surgeon, is relieved from duty at Fort Niobrara, Nebraska, and ordered to Boston, Mass., for duty as attending surgeon and examiner of recruits.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending October 3, 1896:*

BRODRICK, R. G., Assistant Surgeon. Detached from the Franklin and granted leave for two months.

VAN REYEN, W. K., Medical Director. Ordered to duty as member of the Inspection and Survey Board. October 1.

WISE, J. C., Medical Inspector. Detached from duty on the Board of Inspection and Survey and ordered to Museum of Hygiene. October 1.

**Marine-Hospital Service.**—*Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Fifteen Days ending September 30, 1896:*

IRWIN, FAIRFAX, Surgeon. Granted leave of absence for thirty days from October 5, 1896. September 28, 1896.

BANKS, C. E., Surgeon. When relieved from temporary duty at Vineyard Haven, Mass., to inspect unseviceable property at Boston, Mass., then to rejoin station in Washington, D. C. September 22, 1896.

WASDIN, EUGENE, Passed Assistant Surgeon. Granted leave of absence for twenty-eight days from December 4, 1896. September 30, 1896.

BROOKS, S. D., Passed Assistant Surgeon. To assume temporary command of Quarantine Station at Port Townsend, Washington, in addition to other duties for thirty days. September 16, 1896.

GEDDINGS, H. D., Passed Assistant Surgeon. Granted leave of absence for seven days from September 22, 1896.

WERTENBAKER, C. P., Passed Assistant Surgeon. To proceed from Delaware Breakwater Quarantine to Wilmington, Del., for special temporary duty. September 16, 1896.

YOUNG, G. B., Passed Assistant Surgeon. Granted leave of absence for twenty-three days from October 1, 1896. September 22, 1896.

STEWART, W. J. S., Passed Assistant Surgeon. To inspect quarantine establishment of Washington, D. C. September 22, 1896.

NORMAN, SEATON, Assistant Surgeon. To proceed from New Orleans, La., to Memphis, Tenn., for temporary duty. September 24, 1896.

GREENE, J. B., Assistant Surgeon. Leave of absence extended four days, upon expiration of which to proceed to Key West, Fla., for temporary duty. September 30, 1896.

#### Society Meetings for the Coming Week:

MONDAY, October 12th: New York Ophthalmological Society (private); New York Medico-historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); New York Academy of Medicine (Section in General Surgery); Lenox Medical and Surgical Society (private), New York; Microscopical Club of the Buffalo Society of Natural Sciences; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

TUESDAY, October 13th: New York State Medical Association (first day—New York); New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Buffalo Academy of Medicine (Section in Medicine); Kings County, N. Y., Medical Association; Medical Association of Northern New York (annual—Malone); Medical Societies of the Counties of Albany (semi-annual), Chenango (tri-annual), Greene (semi-annual—Cairo), Jefferson (quarterly—Watertown), Oneida (semi-annual—Rome), Ontario (quarterly), Rensselaer, Schoharie (semi-annual), and Tioga (Owego), N. Y.; Newark, N. J. (private), and Trenton, N. J., Medical Associations; Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery.

WEDNESDAY, October 14th: New York State Medical Association (second day); New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Medical Society of the County of Albany, N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society.

THURSDAY, October 15th: Vermont State Medical Society (first day—St. Johnsbury); New York State Medical Association (third day); New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, October 16th: Vermont State Medical Society (second day); New York Academy of Medicine (Section in Orthopaedic Surgery); Brooklyn Medical Society; Baltimore Clinical Society; Chicago Gynaecological Society (annual); St. Louis Academy of Medical and Surgical Sciences.

SATURDAY, October 17th: Clinical Society of the New York Post-graduate Medical School and Hospital; St. Louis, Medical Society.

## Births, Marriages, and Deaths.

### Born.

GARCIN.—In Richmond, Virginia, on Wednesday, September 30th, to Dr. and Mrs. Ramon D. Garcin, a son.

### Married.

BOGIE—MORSE.—In Kansas City, on Thursday, September 10th, Dr. Marcus A. Bogie and Miss Elizabeth M. Morse.

COULBOURN—HOOD.—In Mobile, on Wednesday, October 7th, Dr. Joseph Thomas Coulbourn, of Birmingham, Alabama, and Miss Annie Anderson Hood.

GOLDBERG—JACOBS.—In Buffalo, on Tuesday, October 6th, Dr. Jacob Goldberg and Miss Rebecca Jacobs.

GRINNELL—CATHERWOOD.—In the Presidio, California, on Monday, October 5th, Dr. Morton Grinnell, of New York, and Miss Jennie Stanford Catherwood.

NEUMANN—VOGEL.—In New York, on Tuesday, October 6th, Dr. Ignatz Neumann and Miss Flora Vogel.

VAN GIESON—POOL.—In Jersey City, on Wednesday, January 8, 1896, Dr. Ira Van Gieson, of Greenpoint, Long Island, and Miss Evelyn Pool.

### Died.

ARTMAN.—In Buffalo Creek, Colorado, on Tuesday, September 9th, Dr. Milton Ellsworth Artman, formerly of Rochester, N. Y., aged thirty-two years.

AYRES.—In Pontchatoula, Louisiana, on Sunday, September 27th, Dr. William C. Ayres, formerly of New York, in the forty-fourth year of his age.

BURGESS.—In Summerton, South Carolina, on Friday, September 11th, Dr. Thomas L. Burgess.

HOLSTEN.—In Beaumaris, Canada, on Friday, August 21st, Dr. George Dedric Holsten, formerly of Brooklyn N. Y.

## Letters to the Editor.

### CRATÆGUS OXYACANTHA IN THE TREATMENT OF HEART DISEASE.

CHICAGO, September 10, 1896.

To the Editor of the New York Medical Journal:

SIR: I desire to call the attention of the profession to a new, or rather a lately announced, cure for certain forms of heart disease. Well, there lived in the city

of Ennis, County Clare, Ireland, until about two years ago, a prominent physician named Greene.

Dr. Greene was well and favorably known over the greater part of Ireland and parts of England and Scotland for professional skill and learning, but chiefly for his reputed ability to cure heart disease.

People flocked to him from all parts of the land to be treated for that disease.

He amassed a good deal of money out of his secret remedy, but lost caste with the profession for refusing to disclose his secret. About two years ago he died, and his daughter, a Mrs. Graham, the sole beneficiary of his will, directed the executor of the will to make public the heart cure. This he did, and it was found to consist of a fluid extract made from the *Crataegus oxyacantha* or hawthorn fruit. My brother, who resides within a few miles of Ennis, having informed me of these things, I immediately wrote him requesting that he send me some of the fruit to be used for testing the efficacy of the remedy, which he did.

I made a fluid extract according to the *British Pharmacopæia* and have used it, up to the present, on forty-three patients suffering with various forms of heart disease, and, I must say, with the most gratifying results. I can cite but a few of these cases as illustrating its curative power on that disease.

Case I was that of a Mr. B., aged seventy-three years. I found him gasping for breath when I entered the room, with a pulse-rate of 158 and very feeble; great oedema of lower limbs and abdomen. A more desperate case could hardly be found. I gave him fifteen drops of the fluid extract of *crataegus* in half a wineglass of water. In fifteen minutes the pulse beat was 126 and stronger, and breathing was not so labored. In twenty-five minutes pulse beat 110 and the force was still increasing, breathing much easier. He now got ten drops in same quantity of water, and in one hour from the time I entered the house he was, for the first time in ten days, able to lie horizontally on the bed. I made an examination of the heart and found mitral regurgitation from valvular deficiency, with great enlargement. For the oedema I prescribed *hydrargyrum cum creta*, squill, and digitalis. He received ten drops four times a day of the *crataegus* and was permitted to use some light beer, to which he had become accustomed, at meal time.

He made a rapid, and apparently full, recovery until, in three months, he felt as well as any man of his age in Chicago. He, occasionally, particularly in the change of weather, takes some of the fluid extract of *crataegus* which, he says, quickly stops shortness of breath, or pain in the heart. His father and a brother died of heart disease.

Case II was that of a young woman. I was met in the hallway of her home, as I entered, with the announcement that she was dead.

I went in and found that she was not quite dead, though apparently so. I put five or six drops of nitrite of amyl to her nose and alternately pressing and relaxing the chest, so as to imitate natural breathing, I soon had her able to open her eyes and speak. I gave her hypodermically ten drops of the fluid extract, and in less than half an hour she was able to talk and describe her feelings. An examination revealed a painfully anæmic condition of the patient, but without any discoverable lesions of the heart, except functional.

The pulse was hardly perceptible for twenty minutes after she received the hypodermic injection; after that

lapse of time it grew slowly strong and less numerous, and at the end of half an hour was fairly good.

A chronic dysentery and indigestion, which were responsible for her trouble, having been cured, the heart trouble and nervous state gradually responded to the general improvement until, at the end of ten weeks, the girl was in a perfect state of health.

She received ten drops of the fluid extract of *crataegus*, after meals, three times a day for one month—after that only occasionally. Her heart trouble, though very dangerous, was only functional, and resulted from the want of proper assimilation of the food due, chiefly, to the dyspeptic state and dysentery.

Case III was that of a lady from Louisville. She had come hither and put herself under the care of a faith-cure man, and had grown worse, daily, until she was taken with dyspnoea at the time I was called to her. She could have lived but a short time if relief was not promptly given her. She was suffering from compensatory enlargement of the heart from mitral insufficiency. A married sister and her father had similar trouble, she said. Her treatment was ten drops of the fluid extract of *crataegus* in half a wineglass of water, four times a day, after eating, with a pill consisting of *hydrargyrum cum creta*, digitalis, and squill. When any indication of salivation became evident the pill was omitted until the gums or mouth had become normal. After one month all active treatment, except a tonic, had been succeeded by an occasional treatment only for the next succeeding two months, and which consisted in giving the patient the medicine once or twice daily and only increasing the frequency of the dose when a lowering barometer or heavy atmosphere indicated possible heart trouble. This patient returned to Louisville in three months apparently well, or at least with neither subjective nor objective signs of disease of the heart.

In a letter from her, three months afterward, she said she was feeling well, but that she would not feel fully secure without some of the *crataegus*.

The forty other cases ran courses somewhat similar to the three cited—all having been apparently cured. Yet, I am not satisfied, beyond a doubt, that any of those patients were completely cured, except those whose troubles of the heart were functional, like the second case cited. And it is possible, and even probable, that, in weather of a heavy atmosphere or when it is surcharged with electricity, or if the patient be subjected to great excitement or sudden and violent commotion or exercise, he may suffer again therewith. That the medicine has a remarkable influence on the diseased heart must, I think, be admitted. From experiments on dogs and cats, made by myself, it appears to influence the vagi and cardio-inhibitory centres, and diminishes the pulse rate, increases the intraventricular pressure, and thus filling the heart with blood causes retardation of the beat and an equilibrium between the general blood pressure and force of the beat. Cardiac impulse, after a few days' use of the *crataegus*, is greatly strengthened and yields that low, soft tone, so characteristic of the first sound, as shown by the cardiograph. The entire central nervous system seems to be influenced favorably by its use; the appetite increases and assimilation and nutrition improve, showing an influence over the sympathetic and the solar plexus. Also, a sense of quietude and well-being rests on the patient, and he who, before its use, was cross, melancholic, and irritable, after a few days of its use shows marked signs of improvement in his mental state. I doubt if it is indicated in fatty en-

largement. The dose which I have found to be the most available is from ten to fifteen drops, after meals or food. If taken before food it may, in very susceptible patients, cause nausea. I find, also, that after its use for a month it may be well to discontinue for a week or two, when it should be renewed for another month or so. Usually, three months seem to be the proper time for actual treatment, and after that only at such times as a warning pain of the heart or dyspnea may point out.

Digitalis, in some form, should be used as an adjunct to the cratægus. M. C. JENNINGS, M. D.

#### AN ODD EYE CASE.

SCRANTON, PENNSYLVANIA, September 10, 1896.

To the Editor of the *New York Medical Journal*:

SIR: The following case that I saw some time ago is rather unique in several particulars: J. M., twenty-eight years old, consulted me about a failure of vision in the left eye that had come on suddenly, without any pain or other irritation. The patient, who is a machinist, stated that up to three weeks before I saw him he had been able to see as well with one eye as with the other; that at that time he began working nights under the glare of an exposed arc light, and that he did not seem to see his work so well with the left eye (which was nearest the light). He paid no attention to this, thinking it was only imagination or some passing trouble, till the morning of his call, when, on closing the right eye, he found the left one practically blind. On examination, a few feet away there was no noticeable difference in the cornea; but in the dark the vision was reduced to a bare perception of the candle flame at a distance of ten feet. On ophthalmoscopic examination, the posterior surface of the cornea seemed impervious to light and presented a tessellated appearance, very regular in marking, of a pearly hue, the marking being in the form of diamonds or pointed squares. There was no change in the tension. His smoking was limited to one cigar a week, generally Saturday evening. No specific trouble could be ascertained, and he never had been sick for a day since childhood. What caused the condition? I am of the opinion that it was due to working under the light. Was it not due to the X rays? I should be pleased to learn if any fellow oculist has seen a similar case. I can find nothing like it in the literature on the subject.

W. F. CONNERS, M. D.

### Proceedings of Societies.

#### AMERICAN LARYNGOLOGICAL ASSOCIATION.

*Eighteenth Annual Congress, held in Pittsburgh, Pa., Thursday, Friday, and Saturday, May 14, 15, and 16, 1896.*

The President, Dr. WILLIAM H. DALY, of Pittsburgh, in the Chair.

(Continued from page 469.)

The *Ætiology of Deviations, Spurs, and Ridges of the Nasal Septum*.—Dr. JOHN O. ROE, of Rochester, read a paper on this subject. (See page 477.)

The Operation for Deviation of the Nasal Septum.—Dr. A. W. WATSON, of Philadelphia, read a paper on this subject. (See page 451.)

A *Manometer*.—Dr. WRIGHT demonstrated an instrument for determining the amount of nasal obstruction. He stated that by watching the column in the glass tube, one would see it rise, and by that means could determine the amount of obstruction as registered upon the tube. There were several sources of error. The rapid expiration did not interfere with the fluid. One must be sure that the tubes were clear, and a little experience made this method one of value to the general practitioner who was not able to make a proper diagnosis.

Dr. E. F. INGALS, of Chicago, said: I have been much interested in these papers, and I fully agree with the first paper in what was said about the predisposing causes of the deflection being due to nutritive changes. I believe nutritive changes are the cause of nearly all deflections of the septum; but I think the exciting causes mentioned have very little influence. We all know that now and then everybody gets a blow on the nose, whether he has a deflected septum or not, but the assumption that these accidents cause many of the deviations has been very properly criticised. A few years ago, a priest who had a bent septum and who had been under the care of one of our fellows, told me that he had inquired as to the cause. The physician asked him if he ever when he was a boy received a blow on the nose. He answered that he supposed he had, as he never knew a boy of any spirit who had not. I doubt if there is a man in this room who has not at some time received a severe blow on the nose, yet probably not more than fifty per cent. at most have deflection. To attribute the ordinary deflected septum to a blow is very much like the reasoning I once saw in a homœopathic journal on the wonderful effects of a thousandth potency of arsenic in relieving nervousness. After several doses relief was obtained, which was attributed entirely to the arsenic, but it subsequently appeared that thirty grains of bromide of potassium had been given with each dose. I believe blows upon the nose have very little influence in causing deflection, unless they are followed by protracted congestion. The paper states that Indians seldom have deflection of the septum, but I have no doubt that blows upon the nose are much more frequent among them than among civilized people. Deflections affect osseous as well as cartilaginous portions. The probable reason that the Indians do not often have deflections is that they are constantly out of doors, and therefore suffer less from nasal catarrh, with attendant hyperæmia and supernutrition of the nasal mucous membranes and underlying tissues.

Dr. ASCH, of New York, said: I agree with Dr. Ingals's criticism in regard to the cause of deflection. I do not believe that one case in fifty is due to traumatism. If you consider the character of the deviations that we are called upon to treat, you will see that it would not be possible to have such deviations without some external deformity. The majority of the cases are those in which you have an acute angle looking something like the figure I draw on the board. Traumatism would not produce that. It seems to me that it is rather due to a deformity of the osseous framework pushing the cartilaginous septum down. With regard to the enlargement of the turbinated body, I think Dr. Roe is correct, that it is caused by irritation due to the increased passage of air. Concerning Dr.

Watson's paper, I regret to hear him say that there has been no method suggested for curing deflections of the septum. He evidently has not read the paper I read before this association in Baltimore in 1889, in which I described an operation which has been performed by me in New York over a hundred times, and in nearly every case with success. There are, doubtless, men here who have done this operation, and I should like to put myself on record to the effect that operations have been devised before now by means of which the deformity can be successfully treated. I have brought the instrument with me that I showed at the previous meeting, and which I show you here, and I read a paper in the fall of last year, since which time many successful operations of the kind have been done. I should like permission to describe the operation once more, it being founded on the fact that the only way you can cure is by destroying the resiliency of the septum. (The speaker here demonstrated his instrument.) Two sections are made as nearly at right angles as possible, and the segments which are made are broken up with the finger. I then insert a hard-rubber tube of the kind I have here and the operation is finished. I formerly plugged the nostrils, but the inconvenience arising from it was so great that I substituted the tubes. The operation is done very quickly, and the scissors are employed by me instead of a knife. You can operate without seeing. Push your finger through after the incision is made and break down the segments before introducing the tube. You may not get a cure in every case, for no operation can do this; but ninety-five out of every hundred cases will show good results. You will restore the respiratory function, and that is what you want. Your patient will be able to breathe perfectly well. I simply desire to go on record as having followed out the operation that I reported in 1889.

In response to Dr. Ingals's query as to how a case like that drawn on the blackboard would be treated, Dr. Asch said: Perfectly easy; make one section as I show on the board and another at right angles; push the segments through so that they break up at their base; take a strong forceps and break up the attachments, and then put in the tube. In nine out of ten cases there will be no perforation.

Dr. S. O. VANDER POEL, of New York, said: I was much interested in Dr. Watson's paper, as I have had some experience in the same operative procedure—that is, the reduction of the septum by means of the pin. I have met with the same difficulty that Dr. Asch has referred to—*i. e.*, the resiliency of the septum. In some twenty cases in which I employed the pin the pressure caused by it was so great that it produced great pain and discomfort in wearing, and was also sufficient, in several instances, to produce ulceration, the result being that a fenestra frequently formed, and instead of adhesive inflammation taking place, necrosis and consequent perforation followed. Of course I did attempt to obviate the natural resiliency of the cartilaginous septum. I broke up thoroughly the attachments of the cartilage, but the patient was unable to wear the pin sufficiently long on account of the pressure, and it was almost invariably followed by necrosis. With regard to Dr. Asch's operation, I have used it twice with good results. If the resiliency of the septum is sufficiently broken up under ether, as it should be, an appropriately fitting splint can be worn for a sufficient length of time without inconvenience to the patient. In addition to my own two cases, I have seen a number at the Manhattan Hospital.

Dr. CARL SEILER, of Philadelphia, said: Although I did not hear the papers, the discussion by Dr. Asch and Dr. Vander Poel has given me sufficient insight. It seems to me that Dr. Asch has simply revived an old operation, which was originally introduced before the American Laryngological Association by Dr. Glasgow, of St. Louis, and was afterward claimed by Dr. Sajous. Instead of using scissors Dr. Glasgow used a punch, so as to make a stellate incision into the septum. Evidently Dr. Vander Poel has had bad success with the pin splint, simply because he has not taken into account the fact that if you want to straighten up a fence you must put your posts down low. The fulcrum does not come in the middle of the fence, but at the bottom, and you must put your posts in the ground in order to hold it up. The incision Dr. Asch has described you will find given in the first edition of my book. In 1880 I also described Dr. Glasgow's operation, and mentioned that in order to make the pin a proper splint it should be introduced as near the nasal bone as possible, where the cartilaginous septum is inserted. It should run down from the other side, through the septum, and into the cleft of the two superior maxillary bones. Then hammer them fast. This may sound barbarous and unsentimental, but it is really the most successful and satisfactory method of producing a splint for fractured septum, without producing necrosis of either the cartilage of the septum or the superior maxillary bone. The only precaution that has to be observed is that the pin should be cut off short, or level with the skin. I generally allow from forty-eight hours to three days to elapse before I cut it short. I allow it to project beyond the level of the skin in order to compensate for swelling. There are three patients who have the pins in their noses now, because the skin healed over the end, and the pins sunk so that I could not get them out without making a disfiguring scar. The very fact of these patients still having these pins in their noses shows that if they are properly introduced there is no possibility of necrosis.

In response to Dr. Asch's query as to where the principle of this method, outside of his own book, could be found described, Dr. SEILER said: The principle is the same as in the other operation—that is, make two cuts one longitudinal and one crosswise.

Dr. J. E. H. NICHOLS, of New York, said: The whole matter seems to rest on whether the resiliency of the septum is broken up or not, and it certainly should be broken on all sides. The operation of Dr. Asch is a most excellent one, where the cartilaginous septum alone is involved. In some cases it is necessary to make a compound fracture of the septum, breaking up the cartilaginous septum and the anterior portion of the bony septum into a pulpy mass, so that it can be molded in the fingers. I have seen about two hundred cases of deviation cured by this method, and have personally done over eighty operations. I have used the splint devised by Dr. Berens, of New York, which is made of cork and covered with iodoform collodion. It is non-absorbent, and is worn from eight to ten weeks without any swelling following, during which time there is perfect nasal respiration. I have yet to see a case that can not be cured, and I think the success is due to the fact that the whole septum is broken up. I do not see how good results can be secured unless the resiliency and the surrounding attachments of cartilage are broken up.

Dr. D. B. DELAVAN, of New York, said: I gave the pin operation an extended trial, then abandoned it, as

being much less satisfactory in its results than others, and far more irritating. With regard to the Asch operation, while somewhat similar processes have been proposed before, it remained for Dr. Asch to elaborate a practical method for the relief of these cases. This he has done, first, in describing in practical detail the principles of his method and the various steps by which the work is accomplished; secondly, in devising the instruments necessary for the operation. The patients who have been exhibited by Dr. Asch from time to time amply prove the success of his work. As to aetiology, traumatism doubtless plays an important part in a certain number of these cases, but by no means in all of them, or, probably, even in the majority. Very many of the worst of them are the results of mouth-breathing. If this is not recognized, the most important opportunity for preventing the trouble—namely, by overcoming the mouth-breathing while the children are yet young—will be lost.

Dr. W. E. CASSELBERRY, of Chicago, said: No one now maintains that traumatism is the most common cause of deflection of the septum, yet all regard it as an occasional cause. Adenoid vegetations, in association with a high-arched palate, is another occasional cause; but heredity, I believe, deserves more consideration in this connection.

Dr. ROE mentioned the manner in which ossification took place, sometimes more rapidly on one side than on the other. Why is this so? he asked. When we speak of heredity we are still in the dark, but it goes one step farther back. I recently had three cases under observation: A mother with pronounced deflection to the left and her two sons with identically the same in the same location. It is reasonable to suppose that if heredity is influential in transmitting peculiarities in facial conformation it can also be influential in producing a peculiarly formed septum, which, after all, is simply an intranasal fracture, as subject to the laws of heredity as the external nose.

As to the operation for deflection, as no one case can be assigned in explanation of all cases, so no one operation is applicable in treatment, as cases differ very much. The deflection is sometimes horizontal, sometimes vertical, and again both combined. Some patients require anaesthetics, while others do not. As to Dr. Watson's operation, those who have not seen his drawing may have failed to appreciate the points. For certain horizontal deflections the point that he has made of bracing the deflection by overlapping the cut edges would be applicable. I have used a modified Asch operation, which is designed only for cartilaginous deflections, and I have found it very useful. I have done practically the same thing with a bistoury, making a crucial incision, that one could do with special scissors. I employ cocaine anaesthesia. In young patients it is difficult to insert a cutting forceps or the Asch scissors into the nose, and I have found a bistoury to answer very well. Some pressure is needed to break up the resiliency. I first use iodoform gauze packing to guard against hæmorrhage and as a splint for the first two or three days, and this is followed by the insertion of the Asch tube, which is worn for from four to six weeks.

Dr. MACKENZIE said that he arose to do a dead man historical justice. The principle involved in the operation of Dr. Asch originated with Dr. James Bolton, of Richmond, who years ago described his method of procedure in the *Virginia Medical Monthly*. Dr. Bolton first employed a pair of buttonhole scissors with which

he made the stellate incisions. Subsequently an instrument was made for him by an instrument maker in New York, and from this has developed the apparatus used at the present day.

After the operation it is not always necessary to pack both nostrils. I generally content myself with packing only one. Sterilized gauze answers every purpose. If there is a disposition for the septum to return to its malposition, I have a very thin hollow shell made to fit the narrowed nostril, and through this the patient can breathe with perfect freedom. This can be worn, if necessary, for weeks or months. The operation selected will depend upon the nature of the deflection. No one operation is applicable to every case. Often a case will require two or more different operations before success can be attained.

I do not think the statement of Dr. Ingals in regard to the relative frequency of deflection of the bony septum should go unchallenged by this society.

Dr. W. K. SIMPSON, of New York, said: I am very glad that Dr. Asch did not allow his operation to go unmentioned. I wish to emphasize the success of his operation. Its success depends not only on the operation itself, but the way in which the details are carried out. It has been emphasized before that the first thing is to break up the resiliency of the septum and then to keep it broken up. The splint devised by Dr. Asch and modified by Dr. Mayer, of New York, is almost a straight one. I wish to mention the fact that in stopping a hæmorrhage it is bad surgery to plug the nares with gauze for any length of time, and by using this splint plugging will not be necessary. Two splints are used, one being put on the convex side to retain the parts, and the other on the concave side. Both exercise pressure, and hæmorrhage is very rare. It may be very severe at the time of the operation, but stops immediately after the insertion of the splints. The one on the concave side may be taken out at the end of a day or two. A point that is often lost sight of is that the nose is not plugged at any time and can be freely washed out.

Dr. A. W. DE ROALDES, of New Orleans, said: I agree with the gentlemen who have commended the Asch operation. I was not so much impressed with it at first, but I made a point of calling on Dr. Asch and witnessing the operation. I was also present at a meeting of the Academy of Medicine when three or four cases were presented, and the results satisfied me. I subsequently procured an instrument which I have had occasion to use, and it has pleased me more than any others. In regard to the aetiology, I should like to say that my experience with the negro race is that they are less subject to deviations, and probably their larger nasal space is the cause. I have also thought it might be a question of nutrition and open-air life.

Dr. J. W. GLEITSMANN, of New York, said: Concerning Dr. Asch's instrument, I can verify the statements made, and in cases of marked deviation of the cartilaginous septum I have found his manner of operating more satisfactory and followed by better results than other methods with which I am acquainted. In my opinion, it should be more universally employed.

Dr. CHARLES M. SHIELDS, of Richmond, said: Attention has not been sufficiently drawn to the fact of the combination of deflection of the septum with thickening in many cases. All of the operations get at the same results by different means. I operate with a bistoury, because the incisions can be made where they will give the best results. I think it is most difficult to oper-

ate in those cases in which there is thickening as well as deviation, and I do not believe that any operation under such circumstances, consisting only of going through the septum, will be successful. If you get sufficient space there the thickening will ultimately cause recurrence. I always saw off the thickened part, having previously determined its existence, then make the incisions through the septum with the bistoury, and the parts are kept in position with splints.

Dr. GEORGE A. LELAND, of Boston, said: The first operation for deflection of the septum done by me according to the principles of Dr. Asch's operation, in 1888, but with simply the smooth forceps of Adams and the stellate cutting forceps of Steele, was a good success so far as the septum was concerned. The soft splints sometimes used have not had firmness enough to keep the septum where it ought to be, and the hard splints are objected to because of the danger of sloughing of the mucous membrane where there is pressure. Hence, I have used a hard-rubber, flat, tubular splint, wound with corrosive cotton, and saturated with a two-per-cent. solution of creolin before introduction. These splints, if accurately adjusted, cause no pain and no swelling, and may be allowed to remain for from seven to ten days without odor if the interiors are kept absolutely clean by the use of peroxide of hydrogen or other solvent and antiseptic solutions. I do not mean that the odor can not be perceived by the attendants, but the patient is not discommoded by it. Dr. Watson has given the indications for treatment very clearly.

The factor in the etiology of scoliosis septi mentioned by Mr. Mayo Collier, F. R. C. S. Eng., in a monograph which he kindly sent me in 1892—viz., an anterior obstruction in a nostril, causing a negative pressure behind it, and so a deflection of the septum to that side—is a very important one, and has given me indications for treatment of suitable cases since that time; and it has been my good fortune, by removal of a tumefaction of the hard or soft parts in the narrow nostril, in quite a number of cases, to see the septum return to the median line by the simple restoration of normal breathing.

In some cases of a moderate degree of deflection the use of a plug in the vestibule of the other nostril to create an artificial negative pressure on the wide side has a number of times been successful in my hands in doing what formerly seemed to require operative interference. The patient assists in the process by pressure of the little finger against the projecting part in the narrow nostril.

It is very common indeed to find an exostosis projecting into the narrower nostril from the intermaxillary ridge. These cases require operative interference, since this must be crushed back into the median line before permanent results can be hoped for. When this point has been attended to, and when respiration has been restored to an equal volume in both sides, I do not think it has been my experience to see a single recurrence in upward of sixty cases.

Dr. ASCH said: When I proposed this operation at the Baltimore meeting of the association, in the discussion that followed, Dr. Mackenzie, then president, stated that the same principle had been suggested by Bolton, of Richmond, though it had been attributed to others, but no operation had been presented with the technics of this one. The operations previously described were nearly all declared to be unsatisfactory, and the president found the same fault with Steele's forceps

as I do, one which led me to give it up after repeated trials—viz., that it did not cut through the septum.

Dr. A. A. BLISS, of Philadelphia, said: I should like to refer to an operation employed by Dr. Harrison Allen, which has not been referred to and which applies to cases where there is some thickening and deflection of the anterior end of the vomer, some hyperostosis at that point, which are difficult to overcome. The remarks made to-day apply very little to the bony portion of the septum. Dr. Allen makes an incision through the frenum of the upper lip at its junction with the alveolar process. The lip is then raised, and a chisel is passed upward through the incision and turned backward over the anterior nasal spine. He chisels directly back, through the anterior nasal spine, thus separating the anterior part of the septum from the floor of the nose, and only makes a very slight external wound. If there is much resiliency, he employs, in addition, cross incisions through the cartilaginous septum. The septum is pushed over to the median line by introducing the little finger into the nostril, and is retained in place by a rubber tube which is worn for several weeks. Excellent results have been obtained from this method. It will always give good results in the very difficult class of cases where the deflections are largely anterior, and where the triangular cartilage and vomer are both involved.

Dr. ROE said: No single operation is equally serviceable in the correction of all forms of deviation of the nasal septum. I think the modification proposed by Dr. Watson is a good one and will be found of service in many cases. Dr. Asch's operation is one that can be used for the cartilaginous portion of the septum only, but where the osseous portion also is deflected it is not applicable. In my experience, in the greater portion of cases of deviation of the septum the anterior portion of the vomer and the anterior portion of the vertical plate of the ethmoid are also found deflected and carried over to one side along with the cartilaginous portion. It is mainly in those cases in which there is a dislocation of the triangular cartilage where we find deviation of the cartilaginous portion only, and which is almost invariably the result of traumatism. No one believes that traumatism is the cause in all cases of deviation of the septum; but that it is frequently the cause when the occurrence of the injury may have been forgotten there can be no doubt. In these cases we generally find an enlargement on both sides of the articulation whereas if the deviation is due to defective development it will be found on one side only.

Three years ago I had the honor of bringing before this association a method of correcting deflections of the septum which I have found to serve the purpose in all cases where there is a combined deflection of the osseous and cartilaginous portions, and which, I think, is better than any other method that I am acquainted with. You are doubtless all of you familiar with my method, and many of you have told me of the excellent results you have obtained from its employment. If time permitted, I should, however, be pleased to describe it to you again, as Dr. Asch has had the pleasure of doing with his operation.

Dr. WATSON said: I am glad that there has been such a thorough discussion. In reply to Dr. Asch I would say that I have not seen his original paper on this subject, but from the general idea that I had of his operation I considered that it came under the head of those consisting of multiple incisions with the use of splints, and therefore did not mention it.

I have never employed his method, but have seen one case where his operation was done, about a week after the operation, and to my thinking it was a complete failure. In my opinion it is impossible to so break up the cartilaginous septum that it will not return, more or less, to its original form. It seems to me that the only way to obtain a permanent result is to reduce the size of the septum. I admit that it is difficult to accurately excise a piece in the horizontal line, but it can be done. In the modification which I have described the overlapping of the parts obviates the necessity for removing a piece in the horizontal line, as it reduces the vertical measurement of the septum.

(To be continued.)

### Book Notices.

*In Sickness and in Health.* A Manual of Domestic Medicine and Surgery, Hygiene, Dietetics, and Nursing, dealing in a Practical Way with the Problems relating to the Maintenance of Health, the Prevention and Treatment of Disease, and the most Effective Aid in Emergencies. By GEORGE WALDO CRARY, M. D., FREDERIC S. LEE, Ph. D., JOSIAH ROYCE, Ph. D., JOSEPH HAMBLEEN SEARS, A. B., SAMUEL T. ARMSTRONG, M. D., Ph. D., ALEXANDER B. JOHNSON, M. D., WILLIAM P. NORTHRUP, M. D., FRANK W. JACKSON, M. D., SAMUEL WALDRON LAMBERT, M. D., FREDERICK PETERSON, M. D., Ph. D., HENRY A. GRIFFIN, M. D., ANNA CAROLINE MAXWELL, and J. WEST ROOSEVELT, M. D., Editor. New York: D. Appleton & Company, 1896. Pp. xvi-991.

THIS is not a book of popular medicine in the ordinary sense of the words. Its tendency is not to induce the reader to dispense with the physician when needed; quite the contrary, those who profit by its perusal will be taught the value of trained attendance in sickness, and will meet the medical man half way and with an intelligence which will distinctly lighten his burden. Such a book, intended for popular use, must be so carefully conceived as to avoid a too great indulgence in scientific abstractions and, on the other hand, a too obvious trimming of the sails to attract popular favor. It is one of the most difficult of all literary tasks worthy to popularize scientific subjects.

The book is composed of thirteen articles, contributed by as many writers who are recognized authorities on the subjects of which they treat. The topics vary greatly in their claims on the attention of the reader. To the non-medical mind, anatomy is a dull enough subject, and the bald description of bones, nerves, and blood-vessels should be woven with a thread of practical usefulness, so that the application of the knowledge gained may be more clearly seen.

Physiology is admirably treated, in a manner at once scholarly and comprehensible. The style and individuality of the writer make the article extremely attractive.

Of the section on psychology we need only say that the author has made it so clear and its usefulness so apparent that it becomes an essential link between physiology and mental pathology.

The article on physical training is rather sophomoric in style, but its tendency is good. The amiable author

demands impossibilities with the zeal of a reformer, but the necessity of habit in exercise can not be too often repeated, and the plea for a higher ideal of physical culture will be productive of good results, especially in the family, where as a rule too little thought is given to that side of the education. Food and clothing are dealt with more satisfactorily in the following article.

Hygiene is treated with great clearness and authority. The article contains much information that should be common property. It is astonishing how much has been compressed into a small space, at the sacrifice perhaps of style, but forming, practically, one of the most useful portions of the book.

Surgical injuries and diseases are considered in an article of nearly two hundred pages. From a medical point of view, it is needless to say that the author has done justice to the subject, but he has not succeeded in divesting himself of the manner of the clinic. Detailed descriptions are out of place in a book of this character. Venereal diseases are dealt with also at unnecessary length, although the delicacy of the subject perhaps has led to the omission elsewhere of a consideration of the moral education of the young, a subject of great importance, containing the germ of prevention.

The articles on diseases in general and on kidney diseases and urinary derangements are characterized by the good sense and clearness as well as by the attractive style peculiar to their talented author.

Of diseases of women and midwifery we have only space to say that the subject has been treated with a refinement that should appeal to the readers for whom it is intended.

In the article on nervous and mental diseases, the author has given results of his large experience in the treatment of alcoholism, which should have great weight in showing the laity how inefficient are the numerous "cures" in vogue. At the present time this seems especially necessary in view of the credulity of some of our city officials.

The article on medicines and treatment is pleasantly written and full of good sense. The author's conservatism, even in the case of the objectionable medicine chest, is commendable.

Although the administration of morphine is mentioned where it is demanded, its great dangers are frequently emphasized. The introductory paragraphs and the generalizations with which the article begins have an unusual charm of style and a directness which leave little to be desired. Here, as elsewhere throughout the book, it is shown how regularity, moderation, and common sense are the three essentials upon which rests the prevention of disease.

The article on nursing the sick is full of practical suggestions, given in a simple and attractive manner, drawn from the large experience of the writer. The juxtaposition of the menu and the cut on pages 932 and 933 is unfortunate.

It may be considered that the introduction of technical descriptions and of abstruse terms is a disadvantage in a book of this nature. To a certain extent this is true, but with a few exceptions, some of which have been noted, the text is remarkably free from obscurity, and the non-medical reader will only be the gainer by this introduction to himself. It is as natural, and should be more so, that intelligent people should take as great an interest in their own structure and functions as in those of the plants and lower animals which sur-

round them. As for disease, when it ceases to be made more mysterious than it is, the reign of sober common sense will have begun.

We know of no book better fitted to inspire the mind of the reader with an interest in and a respect for the subtle processes of our being. Finally, it is a book designed to instruct those having the care of the young in the duty they owe to the community, and should fill admirably this important place in domestic literature.

More might have been said of the need of active measures to limit the spread of tuberculosis. It is through such books as this that the medical profession appeals most directly to the public, and it is only through public opinion that such measures may be taken.

The work of the publishers is excellent as to print and paper. The illustrations are numerous, in some instances perhaps too numerous, and good.

*A Manual of Obstetrics.* By W. A. NEWMAN DORLAND, A. M., M. D., Assistant Demonstrator of Obstetrics, University of Pennsylvania, etc. With One Hundred and Sixty-three Illustrations in the Text and Six Full-page Plates. Philadelphia: W. B. Saunders, 1896. Pp. 7 to 760. [Price, \$2.50.]

THIS volume aims to fill a special field, the needs of the student. And it is not too much to say that it does this admirably both by text and by illustration. The author attempts to cover too much ground, if anything, within the limits of a manual. The discussion, for instance, of eclampsia is overburdened with the narration of theories which have no basis or which have been disproved long ago; certainly in a handbook a student cares little for the history of obstetrical advances. Other passages in the book, too, show the depth of the writer's researches and knowledge; but the criticism is that he has tried to compass too much within his prescribed limits.

On the other hand, there is much that is valuable in this manual. The tables of diagnosis, the discussion of abortion, the hygiene of the mother and of the child, the views expressed on puerperal sepsis and on operative obstetrics are all modern and sanctioned by authority.

The book is well written and well got up. The cuts are many of them new, most of them taken from other books. The frontispiece, representing the corpora lutea of menstruation and of pregnancy, is of ancient heritage and much better drawings might have been selected. The author might, also, have referred to Sabotta's recent work on the corpus luteum with profit. The book may be heartily commended to students.

*Deformities. A Treatise on Orthopædic Surgery.* Intended for Practitioners and Advanced Students. By A. H. TUBBY, M. S. Lond., F. R. C. S. Eng., Surgeon to the National Orthopædic Hospital, etc. Illustrated with 15 Plates and 302 Figures, of which 200 are Original, and by Notes of 100 Cases. London and New York: Macmillan & Co., 1896. Pp. xxii-3 to 598. [Price, \$5.50.]

WORKS on orthopædic surgery are now appearing so rapidly that each new comer challenges a somewhat searching scrutiny. Mr. Tubby's treatise produces a pleasant impression of the author's clinical sense, candor, and moderation, but one seeks in vain for any ma-

terial addition to our knowledge. The literature of the last twelve years, and especially the *Transactions of the American Orthopædic Association*, have been freely quoted, and the recognition of American contributions is particularly hearty. The material is well arranged and the conclusions are conservative, and yet the work as a whole can hardly be said to stand abreast of the best modern practice. Mechanical methods are throughout superficially treated of, and the cuts of some of the appliances represent antiquated and obsolete patterns. The absence of chapters on joint disease mars the completeness and practical usefulness of the work.

The author's surgical standpoint may be estimated by the following:

He fails (on page 408) "to see any reason for strongly advocating immediate reposition after tenotomy." There is no mention of subcutaneous osteotomy. In a Macewen's osteotomy for knock-knee the author recommends osteotomies half an inch and three quarters of an inch in width. In the operation for bowlegs a saw is used. For vicious ankylosis at the hip Adams's operation is preferred to Gant's, and both are described as done with a saw.

The book is handsomely printed on good paper, and the excellence of most of the illustrations is to be warmly commended.

*Die Krankheiten der warmen Länder.* Ein Handbuch für Aerzte. Von Dr. B. SCHEUBE, Fürstl. Physikus und Sanitätsrath in Greiz, früherem Professor an der Medizinschule in Kioto, Japan. Jena: Gustav Fischer, 1896. Pp. vi-462.

THE author of this comprehensive work has done a good service in making a compendium, literary as well as scientific, of the diseases of the tropics. With the growth of commercial relations with southern nations, physicians in the north are sure to encounter more and more of the diseases endemic in southern climes. The author divides his work into five parts, grouping the diseases under consideration according to their ætiology. His intelligent treatment of the diseases is fostered by his long residence in Japan and his extended scientific travels in southern countries.

The description of the forms of malarial fever in the South is admirable and illustrates the great differences existing between our comparatively mild types of the disease and the virulent examples it furnishes in hotter countries. The author has been uniformly successful in finding the parasite of Laveran in the most pernicious forms of malarial infection as well as in the milder types.

Among the other diseases described in this work are dengue, beri-beri, pellagra, the various parasitic diseases peculiar to southern countries, the fatal disease, the "red dog" of the Nile region, the fungus disease of India (the "Madura foot"), and the anihum of the Soudan and India.

*Affections chirurgicales du tronc* (rachis, thorax, abdomen, bassin). Statistique et observations. Par le Dr. POLAILLON, chirurgien de l'Hôtel-Dieu, etc. Paris: Octave Doyn, 1896. Pp. 550.

THIS volume gives the results of the clinical work, in diseases of the trunk, of the surgical division of the Hôtel-Dieu under Polaillon's direction, from 1879 to 1895. A rather unusual course is followed, inasmuch as

the material is grouped as to the lesions present. Statistics are given of both operative and non-operative cases. The percentage of deaths is given under each heading. In inflammation of the vermiform appendix and in typhilitis, the death-rate was higher among the patients operated on than in those not so treated; but one gathers from the subsequent text that in the fatal cases the patients were operated upon at a late date. The entire chapter on intestinal work is extremely interesting. The work abounds in the narration of rare and interesting cases and is well worth reading and preserving for reference.

*Traité d'électrothérapie oculaire.* Par le Dr. P. PANSIER, d'Avignon. Avec une préface de M. le Dr. E. VALUDE, de la Clinique nationale ophthalmologique des Quinze-vingts. Paris: A. Maloine, 1896. Pp. iv+479. [Prix, 6 fr.]

This book is composed of excerpts from the literature dealing with electricity in its relations to ophthalmology. The period covered is, briefly, from the sixteenth century to the present time. Many of the more modern observations quoted by the author are as unscientific as those of that age of empiricism when magnetism and the ideas of Mesmer were rife. If we except the galvano-cautery and the magnet used by Hirschberg for the extraction of fragments of iron from the eye, ocular electrotherapy should need no special consideration. Its action on the muscles and motor nerves is familiar, and as for the successes alleged in disease of the iris, choroid, ciliary body, retina, etc., it must be said that the statements made are not proved. It is the old story of failure to eliminate the action of Nature or other agents to which should be given the greater credit. Electricity may be an adjuvant to atropine in iritis, or, with iridectomy and tonic measures, the nutrition of the eye may be improved by electricity; but to say that it alone is to be credited with the cure of many of the cases cited by the author is absurd.

An exception may be made in favor of the treatment of angiomas of the lids and orbit by electrolysis, and possibly the treatment of detachment of the retina by this means may be of use. A larger proportion of cures of recent detachments by electrolysis is alleged than is obtained by other methods, but it must be remembered that in the case of Schöler's method the original statements have not been substantiated by later observers.

This book is not uninteresting, containing as it does some curiosities of literature, but either because the author is oversanguine or because he prefers to allow the reader to draw his own conclusions, it possesses little value as a scientific treatise and is in places decidedly misleading.

*The Diagnosis and Treatment of Diseases of the Rectum.* Being a Practical Treatise on Fistula, Piles, Fissure and Painful Ulcer, Proctidentia, Polypus, Stricture, Cancer, etc. By WILLIAM ALLINGHAM, F. R. C. S. Eng., Ex-member of the Council of the Royal College of Surgeons of England, etc., and HERBERT W. ALLINGHAM, F. R. C. S. Eng., Surgeon to the Great Northern Hospital, etc. Sixth Edition. New York: William Wood & Company, 1896. Pp. xiii+485.

It affords us pleasure to call attention to this latest edition of the Allinghams' well-known work, for in it we are provided with the modernized successor of five

previous editions whose value has been of the greatest. Although the literature of this field is not a scanty one, and though many of the works it includes are of great excellence, we venture to say that none excels this work in the thoroughness of its field and in the simple, comprehensible, and therefore forcible form in which its information is imparted. Opinions differ, of course, and in rectal surgery it would seem that these differences are in some matters pronounced; and for this very reason we rate this work the higher, for, while not lacking in progressiveness, it is, nevertheless, admirably conservative.

*Transactions of the New York State Medical Association,* for the Year 1895. Volume XII.

THESE *Transactions* are doubtless familiar to the greater number of our readers, and the volume for the year 1895 needs therefore only a mere announcement. Suffice it to say that the collection of papers herein presented is one of which the association may well be proud and one from which the professional reader will derive much that is valuable.

*Transactions of the American Association of Obstetricians and Gynecologists.* Volume VIII. For the Year 1895.

THE papers and discussions in this volume cover a wide area, and it is pleasant to note that obstetrics receives its fair share of attention, which is not always the case in societies of this kind. Fascinating as the field of gynecological surgery seems to be, and brilliant as its accomplishments have been, it should not be allowed to obscure the ever-practical and important science and art of obstetrics.

Naturally, the questions which excited the greatest interest and attention concerned the operations for the removal of the uterus and the appendix. By no means all of the speakers concurred in the fashionable method of removing the uterus by the vaginal route, or in the wholesale way in which it was being removed. We stand aghast when we learn that a certain brilliant French surgeon has removed more than six hundred uteri in the past few years.

In perityphlitis, those who are most observing and who have the largest experience are trying to convince the profession that the condition is a surgical one from the beginning, and that the results will, as a rule, be better the earlier the case is submitted to operation. But it must also not be forgotten that, however early an operation is done, in certain individuals with weak powers of resistance the issue will inevitably be a fatal one.

*Transactions of the Southern Surgical and Gynecological Association.* Volume VIII. Eighth Session, held at Washington, D. C., November 12, 13, and 14, 1895. Published by the Association.

THE papers and discussions of this volume evince the same lively interest in the surgical questions of the day that have made this society an element of great educational importance in the South in the previous years of its history.

The volume opens with a reminiscent paper on the late Dr. Marion Sims, and it is very interesting to note the numerous testimonies which the paper elicited of the esteem and love in which that great man was held. The place which he made for himself in the hearts of

the American medical profession is one which any man may well envy, and his memory becomes no less fragrant with the flight of the years since he took his departure.

*Transactions of the Royal Academy of Medicine in Ireland. Volume XIII.*

As usual, this volume contains interesting and profitable reading. Dr. J. W. Moore discusses small-pox and its treatment in a vein of high literary value, and Dr. O'Carroll and Dr. Drury add papers on the same subject. Argyria is discussed by Dr. Tweedy, who finds an excuse for administering silver salts in locomotor ataxia in the good results, ignoring the staining of the tissues. Dr. Heuston describes an operation for malignant disease of the rectum by which the attachments of the levator ani and sphincter muscles are not interfered with. He asserts that incontinence does not result from this operation. Dr. Glenn reports a number of successful cases of saline infusion from the Rotunda Hospital. Unfortunately, he does not specify the manner of infusion, but one would judge that in the majority of cases it was intraperitoneal. He advocates intra-arterial infusion. The quantity infused is unusual, from four to eight pints being employed. The transactions of the sections of pathology, state medicine, and anatomy contain interesting articles.

BOOKS, ETC., RECEIVED.

*An American Text-book of Physiology.* By Henry P. Bowditch, M. D., John G. Curtis, M. D., Henry H. Donaldson, Ph. D., W. H. Howell, Ph. D., M. D., Frederic S. Lee, Ph. D., Warren P. Lombard, M. D., Graham Lusk, Ph. D., W. T. Porter, M. D., Edward T. Reichert, M. D., and Henry Sewall, Ph. D., M. D. Edited by William H. Howell, Ph. D., M. D., Professor of Physiology in the Johns Hopkins University, Baltimore, Md. Fully illustrated. Philadelphia: W. B. Saunders, 1896. Pp. 16-17 to 1052. [Price, \$6.]

*A Text-book of Histology, Descriptive and Practical. For the Use of Students.* By Arthur Clarkson, M. B., C. M., Edin., formerly Demonstrator of Physiology in the Owens College, Manchester, etc. With One Hundred and Seventy-four Original Colored Illustrations. Philadelphia: W. B. Saunders, 1896. Pp. xx-554. [Price, \$6.]

*Water and Water Supplies.* By John C. Thresh, D. Sc. (London), D. P. H. (Cambridge), etc. Philadelphia: W. B. Saunders, 1896. Pp. xv-431. [Price, \$2.25.]

*Royal Infirmary Cliniques.* By Alexander James, M. D., F. R. C. P. E., Physician to the Royal Infirmary, Edinburgh. Edinburgh: Oliver & Boyd, 1896. Pp. 167. [Price, five shillings.]

*A Text-book for Training Schools for Nurses, including Physiology and Hygiene and the Principles and Practice of Nursing.* By P. M. Wise, M. D., Medical Superintendent, St. Lawrence State Hospital, etc. With an Introduction by Edward Cowles, M. D., Physician-in-chief and Superintendent of the McLane Hospital, Boston, Mass. In Two Volumes. Vol. I. New York: G. P. Putnam's Sons, 1896. Pp. xvii-247.

*The Enlarged Cirrhotic Liver.* By Arthur Foxwell, M. A., M. D., Fellow of the Royal College of Physicians, etc. Birmingham: Cornish Brothers, 1896. Pp. 30.

*First Annual Message of Charles F. Warwick, Mayor of the City of Philadelphia, with Annual Reports of Abraham M. Beitler, Director of the Department of*

*Public Safety, and the Board of Health for the Year ending December 31, 1895.* Issued by the City of Philadelphia, 1896. Pp. xxv-241.

*Diagnostic Uroanalysis.* By M. D. Hoge, Jr., M. D., Professor of Histology, Pathology, and Urology, University College of Medicine, Richmond, Va. Richmond: George M. West, 1896. Pp. 7 to 87. [Price, \$1.]

*Report of the Commissioner of Education for the Year 1893-'94. Volume I. Containing Part I.* Washington: Government Printing Office, 1896. Pp. xlvii-1061.

*Degeneration in Criminals as shown by the Bertillon System of Measurement and Photographs.* By W. A. McCorn, M. D., Kankakee, Illinois.

## New Inventions, etc.

### AN EYELID ROLLER FORCEPS.

By W. H. LUCKETT, M. D.

THE accompanying two-thirds-size cut illustrates a new eyelid roller forceps, which can either be used for expressing the contents of the Meibomian glands, preparatory to operation for cataract, or, substituting the corrugated roller for the smooth, the forceps can be used for the expression of trachoma.

To operate, grasp the forceps with the index finger resting in the corrugated socket on the lower bar and the thumb on the corrugated knob on the upper bar.

To express the Meibomian glands, the smooth plate is inserted beneath the lids, and the smooth roller is

rolled or drawn back and forward by the thumb resting on the corrugated knob. To express trachoma, evert the lids and catch with the forceps, the smooth plate on the outer surface, the corrugated roller on the conjunctival surface, and proceed as before. The instrument does not tear the conjunctiva, is perfectly aseptic, and can be taken entirely apart.

By slightly bending apart the two tempered arms the rollers can easily be taken out and replaced.

The corrugated roller is shown full size in the cut. The instrument is made by Tiemann & Co.

## Miscellany.

**Opothopathy in Addison's Disease.**—In the *Presse médicale* for September 19th M. P. Langlois remarks that, whatever may be the mechanism of the disease, he inclines to the theory of suprarenal insufficiency, and consequently he has been led to make investigations in regard to the efficacy of opothopathy in the treatment of this disease.

If the failures, he says, are numerous, it must be recognized that it is in thyroid opothopathy that the attempts give the most favorable results. Since Vasale

and Gley, who made the first experimental thyroid injections, and Murray, who proposed the therapeutical application, clinical observations in the treatment of myxœdema by the injection or ingestion of the extract or of the thyroid substances have been numerous.

The injections of suprarenal extracts made by Brown-Séquard, by Abelson, and by the author on animals deprived of their capsules caused only a slight prolongation of life; but in the animals thus operated upon death was so rapid that all therapeutical attempts seemed to become powerless.

The first clinical trials were made by Abelson, Charin, and Langlois (*Archives de physiologie*, 1892, page 721) in a tuberculous subject who had reached the last stage, and death followed very rapidly. In two cases observed by Langlois after the injection of three cubic centimetres of the aqueous extract every three days there had been an amelioration of the asthenia; but it had been impracticable to continue the treatment in these cases, and, Langlois insisting especially upon rest, it was difficult to say how much had been due to this treatment and how much to the rest. Also in the first case the authors had noticed an abundant diuresis. The same fact having been observed in the thyroid treatment of myxœdema, and even after all organic injections, there was nothing remarkable in it. However, the investigations made by Oliver and Schaffer and by Cibulsky and Nebich with the extracts of suprarenal capsules having shown the tonic action of these extracts upon the circulatory system, it is probable that capsular extracts exercise a more intense diuretic action than other organic extracts. This diuresis, by causing a thorough lavage of the organism, may contribute also to attenuate the intoxication of Addison's disease.

Among the satisfactory cases, says the author, attention may be called to Maragliano's, in which the patients, who were completely asthenic and bedridden, were able to get up and walk after the tenth injection, and to that of Dieulafoy, in which the patient received considerable benefit during the first period of the treatment from injections containing glycerin; and the same was true in the case of a patient who came under Osler's observation. Foa, Pellacani, and Zucco also tried injections of aqueous extracts and had several cases of death which they attributed to the injections. They had investigated for the purpose of ascertaining if these products could exercise an unfavorable action on the organism, and they called attention, in fact, to several toxic symptoms which were observed experimentally in animals.

The injection of capsular extract increases the blood tension, with slackening of the pulse and acceleration of the respiration, according to Oliver and Schaffer. Cibulsky states that the extract, injected in strong doses, causes cerebral and pulmonary hemorrhage. However, says M. Langlois, although these writers admit an action which is especially exercised on the central nervous system, Velich, on the contrary, believes there is a direct cardiac action, which is accompanied, nevertheless, by a vaso-constriction.

Gluzinsky, while studying the toxicity of various extracts, found that those of the suprarenal capsules were much the most toxic. Gourfein reached almost the same conclusion, and Dubois studied the conditions which led to the difference in the toxicity of these extracts. According to Marino Zucco, the toxic substance which acts above all is neurin. Muhlmann identifies its action with that of pyrocatechin, which is, according to him, accumulated in the suprarenal cap-

sules by the substitutive reaction alone of the pyrocatechuic acid which is contained in the blood.

The substitution of the ingestion of thyroid products for the injections which have been commonly practised since Horvitz's communication should lead to a trial of the same method with suprarenal capsules, especially as Schaffer has ascertained that the extract of suprarenal capsules, digested with artificial gastric juice, preserves the physiological properties which he had found in the normal juice. Oliver tried this treatment by the gastric tract, and in two cases he obtained a very distinct amelioration; the subjects increased in weight and the pigmentation became diminished; the gastric symptoms, the vomiting, and the anorexia were completely suppressed. Rolleston also observed good results in a patient to whom he gave forty-five grains a day.

Dupaigne obtained successful results in seven cases, and Bécélère relates a very interesting case in which the lumbar pains and the vomiting disappeared, the pulse improved, and the pigmentation became less. In this case recovery has lasted for eighteen months.

These observations, says M. Langlois, are sufficiently interesting to permit of the conclusion that opotherapy is a legitimate treatment in Addison's disease. The capsules should be given in the form of pulp in preference to pieces of capsules. This pulp is obtained by scraping the capsules which have been cut in two and reduced by boiling. The mode of ingestion may vary; bouillon, unleavened bread, or soup made of peas or potatoes make an excellent vehicle in which to administer it. According to Pettit, says M. Langlois, the capsules of calves or of other young animals are to be preferred, as the glands are more active in the young. Dieulafoy uses the dried glands in capsules of gelose, and that is the way in which Huchard also employs the treatment in neurasthenia of other origin. In cases of anorexia nemata containing the pulp finely minced, according to a procedure employed by Lissier, seem to be indicated in the treatment of diabetes with pancreatic pulp. The amount given should not exceed forty-five grains a day. It is also useful to employ oxygen inhalations, which gave such successful results in Dupaigne's cases. Such is the treatment, says the author, and, although a definitive cure can not be assured, we may hope for some amelioration.

**The Vermont State Medical Society.**—The eighty-third annual meeting will be held in St. Johnsbury, on October 15th and 16th, under the presidency of Dr. C. F. Branch, of Newport. The programme includes the following papers: The president's address—The True Physician, or the Old and the New; Obituary of Professor C. P. Frost, by Professor William T. Smith, of Hanover, New Hampshire; Opium, its Use and Abuse, by Dr. F. W. Comings, of Derby; The Practice of Medicine in 1858 and in 1896, by Dr. Lyman Rogers, of Bennington; The Management of Acute Peritonitis from a Medical Standpoint, by Dr. W. H. Vincent, of Orwell; The Mineral Springs of Vermont, their Therapeutic Effects, etc., by Dr. E. M. Brown, of Sheldon; Twelve Years' Practice of Obstetrics, by Dr. J. Sutcliffe Hill, of Bellows Falls; Obstetrics, by Dr. F. R. Stoddard, of Shelburne; Hernia and its Cure, by Dr. Henry O. Marcy, of Boston; Diseases of the Rectum, by Dr. D. C. Hawley, of Burlington; Inebriety and its Treatment, by Dr. W. S. Nay, of Underhill; A Class of Fatal Cases presumably Due to Intestinal Ptomaines, by Dr. E. D. Ferguson, of Troy, N. Y.; The Operation of

Shortening the Round Ligaments, its Indications and Technics, by Dr. E. H. Ross, of St. Johnsbury; Some Observations on Preventive Medicine, by Dr. J. Henry Jackson, of Barre; Intestinal Obstruction, by Dr. W. R. Prime, of Burlington; Puerperal Fever, by Dr. J. M. Hamilton, of Proctor; The Discovery of Ether, by Dr. W. J. Aldrich, of St. Johnsbury; and The Value of *Cimicifuga Racemosa* in Pregnancy and Labor, by Dr. F. C. Kinney, of Greensboro.

**The Occurrence of Nutritive Fat in the Human Placenta.**—In a preliminary communication published in No. 359 of the *Proceedings of the Royal Society*, Dr. Thomas Watiss Eden says that recently, while examining specimens of ripe placenta for fatty degeneration, he was struck by the regularity of the occurrence of fat in this structure, and especially by the nature and extent of its distribution. He was then led to examine a series of specimens taken at different periods of gestation, with the result that a free deposit of fat was found in ten different placenta, all of which he believes to be non-pathological, and ranging practically through all periods of gestation, from the sixth week up to term.

The method employed for the demonstration of this fat was to take slices from different parts of the placenta, and harden them for a few days in Müller's fluid; then to transfer thin strips, not exceeding one third of an inch in thickness, to Marchi's fluid (a 1-per-cent. solution of osmic acid, 1 part; Müller's fluid, 2 parts) for a week. The pieces were then imbedded in paraffin, cut with a rocking microtome, and stained lightly with safranin, eosin, or logwood and eosin, or mounted unstained. By this process the fat is completely blackened, while the other tissues retain their normal staining reactions, so that the outlines of the fat-containing cells can be distinctly made out. By this method he has been able to demonstrate the constant occurrence of fat in certain well-defined regions of the human placenta.

In the young human placenta, the epithelial covering of the villi consists of two layers, a superficial, nucleated, plasmodial layer, and a deep cellular layer. In a six weeks' ovum he found fat in the form of minute droplets in both these layers, but much more abundant in the former than in the latter. These fat droplets show comparatively little variation in size, and they remain discrete, showing little or no tendency to form larger droplets by fusion; they are confined to the circumnuclear protoplasm, and are never found in the nuclei, which remain unaltered in number, form, and arrangement. The stroma of these villi contains here and there a trace of fat, but it is apparently healthy, and is furnished with well-formed wide capillaries filled with blood. The villi are, in fact, to all appearance healthy. Every villus does not show this deposit of fat, but it is present in very large numbers of them; in every field of the microscope several villi containing fat may be found. The amount of fat also varies considerably.

In a young ovum the plasmodial layer of the villi shows great proliferative activity; it throws out numerous club-shaped processes or buds, which represent the first stage in the development of new villi. These buds very frequently contain large numbers of minute fat droplets. He believes that this is a point of very great importance, showing, as it does, that the deposit of fat occurs in actively growing tissues of undoubted vitality.

In the ripe placenta the proliferation of the plasmodial layer has ceased, and degenerative changes are present in scattered regions. But, of course, the great majority of the villi retain their vitality, and in these

villi a free deposit of fat is present, showing the same distribution and characters as in the young placenta.

He has also found a similar deposit of fat in the serotina. The six weeks' ovum, above referred to, showed very many decidual cells containing minute, discrete droplets of fat in the circumnuclear protoplasm. A placenta of the sixth month also showed an abundant fat deposit in the same region. At term, the serotina shows many degenerative changes, and although it contains fat, it may well be doubted whether, at this period, this is a physiological deposit.

The placenta, indeed, appears to be a storehouse of nutritive fat, just as the liver is. This appears to throw some light on what has long been one of the problems of foetal physiology, viz., the source from which the foetus obtains its supplies of fat. Diffusible substances, such as sugar, salts, peptones, etc., have been supposed to pass by osmosis from the maternal blood in the intervillous spaces to the foetal blood in the villi. But this could not be assumed of indiffusible substances, such as fat. The truth would seem to be that fat is deposited from the maternal blood in the epithelium of the villi, and stored up there by the foetal tissues for their use. No great accumulation of fat occurs, as it appears to be from time to time absorbed and disposed of by the foetal circulation. It is, however, not altogether clear how a deposit of fat in the decidual cells can be made available for the purposes of foetal nutrition.

Since finding this fat deposit in the human placenta, Dr. Eden has begun a series of comparative observations upon the placenta of other mammals. Up to the time of writing, he has examined two rabbits' placenta, one from an early, and the other from a late, period of gestation. In both there was a marked deposit of fat, chiefly in the superficial glandular layer of the maternal placenta, but also, though to a lesser extent, in the processes of the chorionic mesoblast, which form the homologues of the villi of the human placenta.

The author then refers to Apfelstedt and Aschoff's recent discovery of fat in the placenta.

**The New York State Medical Association** will hold its thirteenth annual meeting in the Mott Memorial Hall, New York, on Tuesday, Wednesday, and Thursday, the 13th, 14th, and 15th inst., under the presidency of Dr. Darwin Colvin. The programme gives the following titles: The Technique of Intubation in Children, Some Remarks on the Time for Operation and After-treatment, by Dr. Thomas J. Hillis, of New York County; Functionless Organs, Are there Any? Possible Use of the Appendix Vermiformis, by Dr. Nelson L. North, of Kings County; The Elongation of Retracted Muscles in Clubfoot, by Dr. T. M. Ludlow Chrystie, of New York County; Special Report on Criminology, by Dr. Austin Flint, of New York County; Brief Comments on the Materia Medica, Pharmacy, and Therapeutics of the Year ending October 1, 1896, by Dr. E. H. Squibb, of Kings County; a discussion on Prostatic Enlargement (to be opened by Dr. J. W. S. Gouley, of New York County, propounding the following questions: What is the nature of prostatic enlargement? How is prostatic enlargement recognized? What are the effects of prostatic enlargement, and how may they be counteracted? When is operative interference indicated, and what operations may be safely performed for prostatic enlargement?—these questions to be discussed by Dr. Samuel Alexander, of New York County; Dr. William S. Trowman, of Erie County; Dr. Donald Maclean, of Detroit; Dr. W.

G. Brownson, of Noroton, Connecticut; Dr. Douglas Ayres, of Montgomery County; and Dr. John A. Wyeth, of New York County; The Treatment of Faecal Fistula, with Reports of Cases, by Dr. Frederick Holme Wiggin, of New York County; Amputation of the Lower Third of the Leg with a Periosteal Flap, by Dr. Joseph D. Bryant, of New York County; Suture of the Liver for Incised Wounds, by Dr. Stephen Smith, of New York County; An Operation for Rectal Hemorrhoids and Prolapse by Submucous Ligature, by Dr. Benjamin M. Ricketts, of Cincinnati; The Practical Uses of Röntgen's Discovery as applied to Surgery, with Illustrations, by Dr. Reginald H. Sayre, of New York County; The Treatment of Otorrhœa, and its Importance, by Dr. Edward B. Dench, of New York County; The Relation of Nose and Throat Affections to Diseases of the Ear, by Dr. Frank S. Milbury, of Kings County; Temperature as an Element in Prognosis, by Dr. John Shradly, of New York County; Diphtheria, by Dr. Thomas G. Acker, of Westchester County; On the Treatment of Inebriety, by Dr. T. D. Crothers, of Hartford, Connecticut; Further Remarks on the Domestic Test for Albumin in Urine, by Dr. John G. Truax, of New York County; A New Microtome, and A Successful Plaster-of-Paris Bandage Cutter, by Dr. Sidney Yankauer, of New York County; The Physiological Deductions regarding the Usefulness of so-called Animal Extracts, by Dr. H. A. Haubold, of New York County; Two Interesting Cases of Surgery of the Kidney, by Dr. J. E. Janvrin, of New York County; Recent Investigations concerning Eclampsia, by Dr. William T. Lusk, of New York County; Puerperal Eclampsia Studied with Reference to Pathogenesis and Therapeutics, by Dr. George T. Harrison, of New York County; The Palliative Treatment of Cancer of the Cervix and Bladder in Women, by Dr. Nathan G. Bozeman, of New York County; Rare Complications in Two Cases of Hysterectomy, by Dr. Ely Van de Warker, of Onondaga County; One Point in the Treatment of Endometritis, by Dr. William H. Robb, of Montgomery County; an address in surgery, by Dr. Charles Phelps, of New York County; The Vitality of Cutaneous Epithelium, with a Report of Clinical Observations in Skin-grafting, by Dr. Zera J. Lusk, of Wyoming County; Acute Amnesia, by Dr. William D. Granger, of Westchester County; The Duty of the Public to the Physician, by Dr. William M. Bemus, of Chautauque County; Supplementary Notes upon Tendon-grafting and Muscle-transplantation for Deformities following Infantile Paralysis, by Dr. S. E. Milliken, of New York County; The Medico-legal Aspect of Prison Reform, by Dr. Ernst H. Schmid, of Westchester County; Auscultatory Percussion, by Dr. Louis L. Seaman, of New York County; Druggist *versus* Doctor, by Dr. Henry C. Van Zandt, of Schenectady County; The Peripheral Neuralgias, Traumatic and Toxic, by Dr. Thomas H. Manley, of New York County; The Passing of Venesection, by Dr. H. D. Didama, of Onondaga County; and A Class of Fatal Cases, presumably due to Intestinal Ptomaines, by Dr. E. D. Ferguson, of Rensselaer County.

**Formaldehyde in the Treatment of Gonorrhœa in Women.**—It is stated in one of the June numbers of the *Semaine médicale* (cited in the *Revue internationale de médecine et de chirurgie*, September 10, 1896) that Professor De Smet, of Brussels, has obtained excellent results with this remedy in more than sixty cases in which he has employed it. After washing the vulva with a warm one-per-cent. aqueous solution of formaldehyde

(or formal or formalin), he introduces a speculum and pours into the vagina a stronger solution, one of from two to five per cent. Then with a swab he works the solution into intimate contact with all the nooks and crannies of the vagina and the cervix uteri. If the cervico-uterine cavity is affected, he injects a two-per-cent. solution into it. If the cervix is ulcerated, he places a large tampon of cotton and gauze impregnated with a one-per-cent. solution in the vagina, and leaves it there for two or three hours. These applications are said to be painless. They are to be repeated daily or every second day, according to the features of the case.

In a one-per-cent. solution, formaldehyde exerts a slightly caustic action, which is shown by a blanching of the mucous membrane. In a five-per-cent. solution, especially in a vaginal tampon impregnated with it, it produces a veritable burning of the mucous membrane, but this action is transitory and causes no inconvenience. A diminution of the discharge takes place after a few applications, and it soon ceases altogether. Severe cases, especially those in which there is fungous blennorrhagic endometritis, call for more prolonged treatment and occasionally for operative interference, by curetting, for example, but even in these cases formaldehyde is the most efficacious adjunct that can be used. Its action is so rapid and so sure that it should be used in all cases of gonorrhœa in women.

**Picric Acid in the Treatment of Superficial Burns and Scalds.**—The treatment of such injuries, says Mr. D'Arcy Power (*British Medical Journal*, September 12, 1896), has long seemed to be most unsatisfactory, for they are attended with an unnecessary amount of inflammation, while the act of renewing the dressings is unduly painful. From time to time he has tried various methods of treatment, and has come to the conclusion that the picric-acid treatment is by far the simplest and the most satisfactory. The method is well known in France, where it has been extensively used by Professor Thiery, while Dr. Filleul and Dr. Papazoglou have done their best to disseminate a knowledge of its value. Mr. Power does not therefore claim the least merit for himself, but he finds that so few practitioners know of it that it is perhaps worth while to draw attention to it.

The solution of picric acid is made by dissolving a drachm and a half of picric acid in three ounces of alcohol, which is then diluted with two pints of distilled water. This is a saturated solution of picric acid.

The clothing over the injured part should be gently removed, and the burned or scalded portion should be cleaned as thoroughly as possible with a piece of absorbent cotton soaked in the lotion. Blisters should be pricked, and the serum should be allowed to escape, care being taken not to destroy the epithelial surfaces. Strips of sterilized gauze are then soaked in the solution of picric acid, and are so applied as to cover the whole of the injured surface. A thin layer of absorbent cotton is put over the gauze, and the dressing is kept in place by a light linen bandage. The moist dressing soon dries, and it may be left in place for three or four days. It must then be changed, the gauze being thoroughly well moistened with the picric-acid solution, for it adheres very closely to the skin. The second dressing is applied in exactly the same manner as the first, and it may be left on for a week.

The great advantages of this method of treatment are: First, that the picric acid seems to deaden the sense of pain; and, secondly, that it limits the tendency to

suppuration, for it coagulates the albuminous exudations, and healing takes place under a scab consisting of epithelial cells hardened by picric acid. A smooth and supple cicatrix remains, which is as much superior to the ordinary scar from a burn as our present surgical scar is superior to that obtained by our predecessors, who allowed their wounds to granulate.

Mr. Power has used this method for more than a year in hospital practice among both out-patients and in-patients, and he says he has every reason to be thoroughly satisfied with the results obtained. It is not an ideal method, for it stains the clothes and discolours the hands of the surgeon, but it is a great improvement upon anything else he knows of.

**The American Pædiatric Society's Second Diphtheria Antitoxine Collective Investigation.**—We have been asked to publish the following:

*"To the Profession:*

"The American Pædiatric Society are encouraged to ask the co-operation of the profession in a further collective investigation. Laryngeal diphtheria is believed to furnish a crucial test for antitoxine; the present aim is to ascertain (1) what percentage of persons with laryngeal diphtheria recover without operation under antitoxine treatment; (2) what percentage of those operated on recover.

"The society asks for records of cases of *diphtheria involving the larynx, whether an operation is performed or not, occurring in private practice in the United States and Canada, treated with antitoxine*. It is expected that cases occurring this year will probably be treated with reliable preparations of the serum, that they will be treated early, and that efficient doses will be given.

"In order to secure data which shall make the tables complete, circulars containing blanks for ten cases have been printed and are now ready for distribution. It is desired that physicians shall fill out the circulars as cases occur, not trusting to memory, and shall urge their friends having similar cases to record them. Circulars can be had by applying to the committee (address below). Several groups of cases in the first investigation arrived too late and were lost to the report. It is desired that circulars as soon as filled (ten cases) be returned to the committee. The collection of cases must close at the end of March, 1897.

"The second report is designed to be a study of cases occurring between the closing of the first report, May 1, 1896, and the closing of the present collective investigation, April 1, 1897.

"For extra circulars (blanks), for returning circulars (filled out), and for further information please address the chairman of the committee,

"W. P. NORTHROP, M. D.,

"57 East Seventy-ninth Street.

"New York, N. Y."

At Dr. Northrup's request, we here reprint a portion of the record of the action taken by the society on the first report, as follows:

#### THE ACTION OF THE SOCIETY UPON THE (FIRST) REPORT.

(1) *Dose*.—For a child over two years old, the dose of antitoxine should be, in all laryngeal cases with stenosis, and in all other severe cases, from 1,500 to 2,000 units for the first injection, to be repeated in from eight- to twenty-four hours if there is no improvement; a third dose to be given after a similar interval if necessary. For severe cases in children under two years, and for mild cases in those over that age, the initial dose

should be 1,000 units, to be repeated as above stated if necessary; a second dose is not usually required. The dose should always be estimated in antitoxine units and not in the amount of serum.

(2) *Quality of Antitoxine*.—The most concentrated strength of an absolutely reliable preparation.

(3) *Time of Administration*.—Antitoxine should be administered as early as possible on a clinical diagnosis, not waiting for a bacteriological culture. However late the first observation is made, an injection should be given unless the progress of the case is favorable and satisfactory.

#### Artificial Serum for Washing out the Serous Cavities.

—M. Mengus (*Indépendance médicale*, July 22, 1896; *Revue internationale de médecine et de chirurgie*, September 10, 1896) relates two cases. The first was a case of hydrocele of the tunica vaginalis testis that had relapsed after the employment of an injection of tincture of iodine. It was cured by injecting a boiled and filtered 0.70-per-cent. solution of sodium chloride at the temperature of 104° F.

The second case was one of ascites in a patient with heart disease. Paracentesis had had to be performed six times in the course of five months, and the man was becoming cachectic. The seventh puncture was followed by the injection of about a quart of the same solution at the same temperature. After massage, about three quarters of the amount was withdrawn. The patient regained his general health, and at the time of the report, three months afterward, no further effusion had taken place.

**Infanticide and Hysteria.**—The *Indépendance médicale* for September 16th condenses from the *Archives de neurologie*, No. 102, an account of a case showing the difficulty of estimating the degree of a woman's moral responsibility at the time of her delivery. A laboring girl living in the country, of gentle manners, had already had one child, which she loved and was bringing up properly, when she gave birth to another viable child, which she strangled. Her neighbors informed against her and she was arrested. At first she denied that she had been confined; then she admitted the confinement, but continued to deny the infanticide, which the report of the medical examiner demonstrated with certainty. Shortly after her incarceration she had delirious attacks. M. Callerre, who was charged with the examination, concluded that she was not insane and had not been at the time of her crime; that she was, however, affected with grave hysteria, and that the disease had caused in her a real impairment of mental balance which should be taken into account in seeking to ascertain her moral responsibility. After having considered this report, the public minister abandoned the prosecution, thinking no doubt that before a jury it could end only in acquittal pure and simple.

#### The New York Hospital Training School for Nurses.

—A reception was held in the administration building, No. 8 West Sixteenth Street, on Wednesday evening, October 7th, by the graduating class, consisting of Miss Frances H. Coe, Miss Mary Vroom, Miss Anna L. R. Mines, Miss Georgia L. Wilkie, Miss Susan V. Gifford, Miss Anne A. Williamson, Miss Isabel H. Peet, Miss Mary E. Hutchison, Miss Fannie L. Morris, Miss Annie E. Parsons, Miss Maude H. Walker, Miss Florence Taylor, Mrs. Margaret L. Rogers, and Miss Florence H. Linton.

Original Communications.

FURTHER NOTES ON  
THE PATHOLOGY AND TREATMENT OF  
GRAVES'S DISEASE.

By W. H. THOMSON, M. D., LL. D.,  
PROFESSOR OF THE PRACTICE OF MEDICINE  
IN THE NEW YORK UNIVERSITY.

(Second Article.)

THE various hypotheses about the pathology of Graves's disease which would ascribe it to some affection of the sympathetic, or of the bulbar centres, etc., have been gradually abandoned of late from lack of characteristic anatomical changes being discoverable anywhere in the nervous system which could be demonstrated as holding a constant relationship to the disease. Recently, however, the striking clinical contrasts between the lately demonstrated affection myxœdema and Graves's disease naturally have given origin to a new theory of the latter as the exact opposite of the former. For, whereas myxœdema is caused by atrophy of the thyroid gland with cessation of its secretion, Graves's disease is supposed to be due to hypertrophy of the thyroid gland and excess of its secretion. One of the most recent advocates of this theory, Dr. M. Allen Starr (*Medical News*, April 18, 1896), points out first that the clinical features of the two diseases are so opposed to each other, symptom for symptom, and the condition of essential cellular atrophy in one is so matched by cellular hypertrophy in the other, that we may properly conclude that an excess of thyroid juice poured into the blood by the enlarged gland is the primary cause of the complaint. In answer to the objection that the severity of the symptoms in many cases of Graves's disease does not bear any appreciable relation to the condition of the gland as regards hypertrophy, Dr. Starr answers that a gland may be secreting excessively without appearing at the time to be enlarged, and he instances the parotids during salivation as an illustration.

I have little objection to this theory, except that it is advanced as an ultimate fact in which we may rest as we do when we come to ultimate facts. One effect of such satisfaction with the theory is to act thereupon, and propose to excise the misbehaving gland. But this is too much like telling a patient with salivation that he has too active parotids, and that it may be needful to cut them out on account of their overactivity, instead of asking first why a secreting gland should pour out an undue quantity of secretion. We shall be answered, of course, that such poisons in the blood as mercury or jaborandi are too well known causes of salivation to justify any one in leaving out a sialogogue in the circulation as the probable cause of this particular hypersecretion. But why should the thyroid gland be considered capable of simply exciting itself to a fatal activity?

What parallel instance is there anywhere in the glandular system of primary and spontaneous overaction? To this it may be replied that glands which discharge their secretions through ducts like the parotids are not the proper counterparts of the thyroid, which belongs rather to the ductless glands, like the spleen and the adrenals. The spleen easily enlarges like the thyroid, and the effects of its disorders are often very marked. Splenic enlargement also from malarial infection, etc., often varies remarkably from time to time, just as the thyroid does in Graves's disease. But if such analogies between the engorgements and hypertrophies of these two glands respectively prove anything, they simply render it probable that supersecretion in a ductless gland is as much dependent upon something circulating in the blood as with any other gland, such as the kidney in diabetes. Moreover, as chronic irritation sometimes produces such an interstitial hypertrophy of the spleen as to render splenectomy in some cases advantageous, so may the thyroid become likewise permanently overgrown, and hence, in a few cases, its partial excision may be useful. We can the more readily grant this because of the recent advances in our knowledge of the speedy adjustment of the system to removal of large amounts of adenoid or glandular tissue by the vicarious action of accessory glands on the one hand, or by rapid regeneration of the original gland tissues from apparently insignificant portions left behind. The spleen, in fact, seems as capable of renewing itself as the amputated claws of a crab. In dogs it may be excised to the extent of leaving only a portion not exceeding two drachms; and yet in six months the whole organ will be found regenerated (*Virchow's Archiv*, Bd. cxli, p. 201). Likewise, it is very probable that accessory thyroid glands may soon grow, to furnish in many cases all that is needed by the economy, after the main portion of the thyroid has been removed, a fact which has already been proved experimentally in animals by Gley,\* Hurtle,† and others. How little gland tissue is required to supply a ferment of vital importance to the system is shown in the case of the pancreas. As is now well known, total extirpation of the pancreas inevitably causes fatal diabetes in dogs and other animals, which is not due to suppression of the secretion of the pancreatic juice, for this may be prevented from entering the intestine by ligation of the pancreatic duct, or by destroying the cells which elaborate this secretion by injecting the duct with plaster of Paris, and yet in neither case will diabetes be produced. Nor will diabetes follow if three fourths of the pancreas be excised, while it certainly follows if the remaining fourth of the gland be then removed; all of which shows that the ferment which is necessary for the proper metabolism of the saccharine elements is the

\* *Archives de physiologie*, Paris, October, 1893.

† *London Journal of Longevity*, July, 1894.

product of cells in the pancreas which are wholly distinct from the cells in it which elaborate its ordinary secretion, and, moreover, that these ferment cells are sufficient, though relatively so few in number. We should be prepared, therefore, to admit that partial thyroidectomy might be of service occasionally in a few cases of chronic Graves's disease without its proving in the least that Graves's disease is primarily due to hypertrophy of the thyroid gland, any more than an enlarged spleen in a patient who has suffered from chronic malarial disease is due to such a thing as spontaneous overaction and hypertrophy of that viscus. For it may be very properly asked here, When are affections of the spleen primary, and the cause rather than the effect of toxæmia, or else of disease elsewhere than in the spleen? In comparison with secondary enlargements of the spleen from intoxication of the blood, primary hypertrophy of the spleen is so rare that its very occurrence is extremely doubtful.

As was explained in my former communication, my attention was first directed to the possible connection of the essential symptoms of Graves's disease—notably the evidences of general vasomotor paralyses, tachycardia, and tremor—with the presence of absorbed ptomaines in the blood, by the unmistakably beneficial effects of a particular article of diet, conjoined with total abstinence from meat in a severe case of the disease. The relation of the symptoms to the food, rather than to the thyroid gland of the patient, was so repeatedly shown in the course, and finally in the fatal termination of the disease, that I beg leave to cite the clinical details again. With this patient I had previously tried a great variety of recommended remedies. Belladonna, arsenic, silver nitrate, digitalis, the bromides, and the iodides had been given in turn without satisfactory results. The diarrhoea continued for many weeks unchecked by astringents, and the emaciation increased with the rapid pulse, excessive nervousness, and insomnia. At last I recommended a complete change of diet, and ordered that the patient, who was now confined to her bed by her weakness and tremor, should be fed exclusively with matzoon and stale bread. The change for the better on this diet was surprisingly rapid and progressive. The diarrhoea stopped without medicines, both her nervousness and sleeplessness improved, and finally the pulse became remarkably lessened. After four months she had so much improved that, contrary to my advice, she discontinued the matzoon and began to resume a meat diet, of which she always had been fond. Two months after this, on her return from the country, I found that all her symptoms had recurred, including the diarrhoea. She again was put on matzoon, and again she improved, and this time she continued the milk for about six months, with such a gain in flesh and color that she felt that she was well. She then went back to her ordinary diet, and I did not hear from her for some time, when I was called, to find her now worse

than ever, because of the development of mental symptoms of both irritability and obstinacy, which she had not shown before. She declared that she would rather die than take the matzoon, and nothing would persuade her to take milk in any form. One day I was sent for to see her because she seemed to be so low. I found her pulse to be with difficulty countable, and she had delirium with hallucinations. While I had my finger on the pulse, trying again to count it, it suddenly stopped, her pupils dilated, and the patient was dead with scarce a perceptible struggle.

Now in this case a change of diet effected what drugs had quite failed to do; and then a first return to a meat diet brought back a return of the disease, then to be again and unmistakably arrested by discontinuing meat and resuming milk; and, lastly, a second return to meat brought back a fatal return of the disorder. In such an instance as this it is as difficult to deny a causal relation between the food taken and the resultant symptoms as it would be in a case of diabetes upon restriction and then upon indulgence in starchy food. Nor, upon a similar showing again and again in other patients with Graves's disease, as detailed in the present paper, do we see any more reason to charge the thyroid gland with being the one cause of the systemic symptoms than we would ascribe the emaciation and fatal weakness of diabetes to overaction of the kidneys. There must be some reason for the overaction of these glands in either case, and if diet markedly influences that overaction in both, respectively, then the primary disorder must be in food assimilation and not in the glands. If the whole train of the symptoms of Graves's disease can be relieved best by letting the thyroid alone, and directing attention instead to the proper management of the alimentary canal by appropriate diet and by the administration of intestinal antiseptics, then the origin of the auto-infection is much more likely to be in the alimentary canal than in the hypothetical and unexplainable hypersecretion of the gland which, on any view of its little-known functions, can hardly be called an excreting gland.

The only considerations which are adduced with plausibility in support of thyroid hypersecretion as the cause of Graves's disease are the effects of overdoses of thyroid extract, and some reported cases of apparent cure of Graves's disease by more or less extensive removals of the hypertrophied gland. It is true that the administration of thyroid extract does produce a quasi-febrile state, with symptoms of arterial and cardiac excitement. Thyroid extract, therefore, aggravates in patients with Graves's disease all their more characteristic symptoms, as happened in Case XI of this report, in which the patient had the extract prescribed for her by a Boston physician with the effect, as she maintained, of becoming much worse from it.\* But while it may be

\* J. J. Putnam (*Brain*, 1894), however, reports a case in which it seemed to do good, and such cases are also reported by other physicians, both European and American; but I should rather ascribe such results to

admitted that the natural secretion of the thyroid gland may be of the nature of a vasomotor excitant, and that an undue quantity of it in the blood may produce corresponding symptoms, yet this is going but a little way toward explaining why its secretion should ever be in undue quantity for months at a time. Nervous irritation can scarcely account for it, for what can keep up such a permanent irritation? As Fodge remarks: "Some writers have endeavored to account for all the phenomena of Graves's disease on a theory of irritation. But it is a sufficient objection to such a view that a primary irritation of a nerve centre, lasting for months or years unchanged, is as yet unknown to pathology."

On the other hand our knowledge, though still too imperfect, about the corrective action of the liver, spleen, and lymphatic glands against auto-infection during the processes of digestion and of metabolism of the body renders it just as probable that the first cause of thyroid overactivity in Graves's disease is due to a greater demand than normal upon the gland to neutralize the presence of absorbed poisons, just as salivation means a poisonous excess in the blood of excitants of the parotid cells. Moreover, that a ductless gland once hypertrophied may continue to act injuriously after the original cause of its overaction has diminished or ceased is shown in the benefit which has followed in some cases upon the removal of the spleen, but I hold that, after all, time is yet to show whether the relief is permanent, and whether such surgical treatment of Graves's disease is not more in the direction of treating the effect instead of the cause of the disease.

Meantime it seems to me that the clinical facts militate strongly against any exclusive thyroid pathology of Graves's disease. As has been already conclusively shown, there may be nothing in a fatal case of Graves's disease to suggest that there was anything the matter with the thyroid. Dr. Starr's supposition that, nevertheless, in such cases the gland may be secretly pouring poisonous quantities of its juice into the blood, has the advantage of all gratuitous hypotheses that they can be neither proved nor disproved. But, as we have already contended, the absence of any condition or symptom from an unmistakable case of a given disease, no matter how prominent it may be in other cases, at once proves that it holds only an accessory and not an essential or causative relationship to the malady. Exophthalmic goitre, without either exophthalmia or goitre, shows not only that we have chosen a most unlucky name, but also that we may have fixed upon the wrong seat altogether of the complaint. Goitre is an enlarged thyroid, but if the thyroid will not enlarge, or does so and then subsides again without any reference to the other symptoms, it indicates as plainly as any clinical

symptom can indicate that at the most it is a common accompaniment rather than the essential element in the disease. Thus, in Passler's series of fifty-eight patients at the Jena Poliklinik, ten had no goitre and thirty no exophthalmia.\*

Nor does the most recent verdict of pathological anatomy teach any other lesson, for different observers vary as often in their accounts as clinical observations do with regard to the conditions found in the thyroid gland. Professor Greenfield † finds great hyperplasia of the secreting structure, and argues that this proliferation suggests increase of secretion. On the other hand, Joffroy and Acard ‡ give the results of six autopsies. The different thyroids presented a great diversity in appearance, but according to them there is no clear line of distinction between the condition of the thyroid in Graves's disease and in simple bronchocele. Vanderhelde and le Bœuf, § from their examinations of the thyroid in four cases, emphatically reject the theory of increased thyroid activity, stating that the goitres in their cases resembled anatomically ordinary goitres. A. Maude, in a series of valuable papers, || says that "There is a gradual growth of the opinion that the symptom complex is due to the production (or non-elimination) in the thyroid itself of some toxine which acts on the whole nervous system, but that we are in the dark as to whether this morbid change is primary or secondary to some vasomotor disturbance elsewhere."

In his second communication, however, he suggests that "this toxine may be first formed in the alimentary canal, and then remain in the circulation on account of excessive disturbance of the thyroid." So far, therefore, as the histological condition of the thyroid in persons dying with Graves's disease goes, it does not give any clearer indications of the cause of its engorgement, when it is engorged, than any other viscus—*e. g.*, the spleen—in a like state.

What the functions of the thyroid gland are in health can be surmised only from the symptoms which occur upon its atrophy, or from thyroidectomy, either on account of disease in man, or experimentally in animals. Now, whatever be the explanation of the phenomena of myxœdema, there can be no doubt that as important a relation has been experimentally demonstrated of the thyroid to the assimilation or metabolism of some of the nitrogenous elements of food as in the case of the pancreas to the assimilation of the saccharine principles. As mentioned in my former communication, Breisacher finds that meat and meat extractives exert a poisonous influence on dogs after thyroidectomy. Ewald found the same results in dogs, but less in rabbits, whereupon, suspecting that the dif-

\* *Deutsche Zeits.*, Heidelberg, B. vi, p. 21.

† *British Medical Journal*, December 9, 1893.

§ *Journ. de méd. de Bruxelles*, March 3, 1894.

|| *Brain*, 1894. *British Medical Journal*, October 21, 1893; June, 1896.

the fact that the thyroid was beginning to atrophy from previous overstimulation, for myxœdema as a sequel of Graves's disease is by no means rare.

ference was due to the difference between these animals in their food, he experimented upon pigeons and found that in their removal of the thyroid did not affect their health. Benissovich\* finds that thyroidectomized dogs succumb on a meat diet, while the number and intensity of the symptoms are diminished on a milk diet. Rosenblatt,† in an extensive series of similar experiments, strongly emphasizes the poisonous effects of a meat diet. Moritz,‡ of Vienna, also points out, in a series of observations on cases of congenital absence of the thyroid gland, that the consequences do not arise till the feeding is no longer with milk.

Clinically, also, from Charcot down, it has been repeatedly reported that a milk diet proves beneficial in Graves's disease. Now it is a significant fact to which Chittenden has drawn attention, that a smaller proportion of bacteria are found in the fæces, both in animals and in man, when fed upon milk than when fed upon any other diet, whether animal or vegetable. These facts, taken in connection with the constant presence of digestive disturbance, notably of persistent diarrhœa, are certainly suggestive of gastro-intestinal auto-infection from products of the digestion, particularly of meat and similar highly nitrogenous articles of food. This relationship to digestive disorder is further borne out by the great preponderance of female compared with male patients with this disease. It would be difficult to imagine that the thyroid itself differs so much between the sexes, but the digestive disturbances of women, both at the beginning of menstruation and at its cessation, are exactly paralleled by the greater frequency of Graves's disease occurring in women coincident with the influence of these periods.

*Treatment.*—My treatment of Graves's disease, based upon the view of its origin from gastro-intestinal ptomaine poisoning, is as follows: 1. I regard the management of the diet as important in this complaint as it is in diabetes mellitus, meat being as poisonous in Graves's disease as saccharine food is to diabetics. As in the latter malady a brief indulgence in starchy food is often followed by a prolonged increase in sugar excretion, even after a strict diet has been resumed, so I have noted repeatedly how long it takes a patient with Graves's disease to recover from a short indiscretion with meat. A disinclination to keep to milk as the chief article of food is always discouraging, and it was in the two fatal cases reported that the patients positively refused to continue it. It is well, therefore, to begin by insisting upon the absolute necessity of the milk diet being kept up for two years, if the patients expect to get well. It is to a departure from this rule that I would ascribe the occurrence of either relapse or failure of cure. Such being the relation of milk to the cure of the disease, it becomes essential that the milk itself be artificially

made digestible. It is from neglect to do this that this regimen ever proves unsatisfactory. Now it is doubtful whether the majority of adults can digest fresh milk in any quantity continuously, unless the stomach is spared the task of the initial curdling of the milk with its own juices, which is a necessary preliminary to its final digestion. At least that would seem to be the verdict of mankind in all cases where milk is the only staple of entire peoples, such as the Tartars, Bedouins, and other pastoral peoples, who invariably ferment the milk before using it, the ferment in each case being derived from yeast. As stated in my former article, this fermented milk is probably the most digestible food that can be found, and I have relieved more cases of vomiting from organic diseases of the stomach with it than by any other one article.\*

Where matzoon is not procurable, several of my patients have done very well with peptonized milk. Lactic acid and pepsin may also be taken after fresh milk, though, in my opinion, not quite so good as Fairchild's peptonic powders. Others again have had recourse to equal-part dilutions of milk with Vichy or limewater. Besides the milk diet I allow a moderate use of fish, and no more than one egg a day. Bread may be taken freely. Among the vegetables, potatoes, corn, beans, and peas are injurious if there be a tendency to diarrhœa. When this complication has persisted for some time, care has to be taken to avoid both vegetables and fruits. Asparagus is mischievous, and often oatmeal also, but tomatoes in salad with lettuce generally agree. I allow no pastry or cakes, except gingerbread, which seems to agree very well, taken with the milk, perhaps on account of the antiseptic effect of the ginger. Of the beverages, I would prefer that neither coffee, tea, nor cocoa be taken. One patient of mine brought on quite a relapse with beer, and I would only use spirits to ward off syncopal symptoms.

As to the medicinal treatment, I can not speak too highly of the systematic use of mercurial purgatives. Repeatedly have I known the rapid pulse to fall from thirty to forty beats after their action, and, as in the toxic diarrhœa of typhoid and scarlet fevers, I know of no

\* With a little practice this milk, called *lben* by the Arabs and *matzoon* by the Turks, can readily be made anywhere. Half an ordinary yeast cake is broken up in a pint of slightly warmed fresh milk. This should be put aside in the kitchen for twelve hours, until it has begun to curdle. A proportion of one fourth of this fermented milk should be stirred in three fourths of warmed fresh milk and set aside as before, when, in summer at least, it will be fermented in twelve hours, and could then be used but for the bitter taste of the yeast still perceptible in it. A third specimen, made in the same proportion from this second one, will then generally have only the slightly acid flavor of good matzoon. After this, all that is needed is to keep enough matzoon from each day's making to ferment the next day's supply. When it is thus curdled it should be well stirred and then put in a refrigerator to prevent its becoming too sour. It is well, however, not to have it too cold when used. It should be smooth like cream, and eaten with a spoon like soup, rather than drunk. Kumyss, the Tartar preparation, is matzoon bottled up, and this contains a good deal of carbonic acid. Being fermented longer than matzoon, it is usually more sour to the taste.

† *Revue des sciences médicales*, Paris, October, 1895.

‡ *Wiener med. Wochenschrift*, Nos. 12 to 15, 1895.

remedy so effective against the looseness of the bowels in Graves's disease. I usually prescribe for this a blue pill, followed by a saline, or a grain and a half to two grains of calomel, rubbed up with forty grains of sugar of milk, then divided into six powders, one to be taken every fifteen minutes till they are finished, and a saline administered three hours after the last dose. This mercurial action may be taken regularly once a week. Besides its effect in reducing the tachycardia it seems to improve markedly both the digestive and the nervous symptoms.

The chief medicinal treatment, however, is in the systematic and unremitting use of intestinal antiseptics. During the past two years I have been very favorably impressed with the action of phenol bismuth, the prescription being—

℞ Phenol bismuth..... 3 iv;  
Sodium benzoate,        }  
Bismuth subcarbonate, } .....āā 3 ij.

M. Div. in capsul. xlviii.

Sig.: Two an hour after meals.

Naphthol bismuth may be substituted for the phenol preparation from time to time. Another prescription is—

℞ Salol..... 3 j;  
Ichthyol..... 3 ss;  
Sodium benzoate,        }  
Bismuth salicylate, } .....āā 3 ij.

M. Div. in capsul. xlviii.

Sig.: Two an hour after meals.

I have also used benzozol in doses of from five to ten grains, but care should be taken that the larger dose does not disturb the stomach.

I am sure that these intestinal antiseptics exert a specific control over the vascular and cardiac disturbance in Graves's disease in marked contrast to the inefficiency of cardiac sedatives. I have never seen any indication of their acting injuriously upon the kidneys, or upon any other organ, though continued without interruption in the above-mentioned doses for months at a time. Along with their effect upon the heart, they appear to affect just as favorably the other numerous nervous symptoms of these patients, such as insomnia, tremor, and agitation, thus indicating their action to be essentially antitoxic. Of the nervines, strophanthus, in doses of five to ten drops of the tincture, may be given as an adjuvant, and for nocturnal attacks of dyspnoea and palpitation ten drops of the tincture of belladonna. Digitalis I have never found of any use. In some cases of violent overaction of the heart I have prescribed five drops of the tincture of aconite night and morning. With treatment guided by these principles, my experience leads me to say that in its early stages Graves's disease is an eminently curable disease, responding promptly to such measures, and that it is very promising, even with the worst cases, if sufficient time be allowed to bring the patient under its influence and then have it faithfully

persevered in. Being, however, essentially a digestive disorder, we might expect it often to subside spontaneously, or to present occasional improvements and then relapses, as digestive disorders so frequently do. This will account for the great variety of measures recommended for its cure, because—*e. g.*, chorea—the oftener a disease gets well of its own accord the longer the list of its reputed remedies. The therapeutic test, then, is the effect in the severest and most threatening instances of the complaint, and in such cases of Graves's disease I am confident that the above-outlined course of treatment will fully stand the test.

As to the results of more or less extensive surgical operations on the thyroid in Graves's disease, Dr. Starr has collected one hundred and ninety cases. Of these, seventy-four are reported as completely cured, some having been watched subsequently from two to four years; forty-five are described as improved, and three as not benefited. Twenty-three, however, died immediately after the operation, with symptoms of sudden rise of temperature to 105° to 107°. Dr. Starr thinks that as death was not due to hemorrhage or want of antiseptic precautions, it is best explained as a result of a sudden poisoning by excessive absorption of thyroid juice during the operation, perhaps from the necessary handling of the gland, increased absorption by torn vessels, or a supersecretion due to the ether used for anaesthesia. This statement, it will be seen, has to rest upon quite a number and variety of theories. 1. The thyroid secretes a hyperpyrexial poison, which it never did before, as the tachycardia of Graves's disease is characteristic because it is non-febrile. 2. This poison is not secreted, or at least absorbed, from the cut surfaces in the operation, except in those who die, for not a case of hyperpyrexia is mentioned in the histories of those who probably were equally cut but who recovered. 3. Therefore, the thyroid secretion in Graves's disease, if absorbed directly from the cells of the gland into the blood, acts very differently from the same on a cut surface. 4. The administration of ether may have made the quantity of the secretion just then excessive. To me it seems that patients with serious Graves's disease ought to be expected to die readily from such a capital operation as thyroidectomy, for they often die of heart failure simply from sitting up. I do not know of any class of patients more unpromising for surgical operations than they are at any period of the malady. And as to the hyperpyrexia, that does not need a toxine to explain it, for similar hyperpyrexia, ending in death, has been repeatedly recorded after such simple operations as washing out the stomach and the pleural cavity. These cases, of course, are not due to toxins, but are explicable as resulting from reflex disturbance of bulbar centres caused by totally unusual afferent impressions from the stomach and pleura respectively. As all experimenters agree that thyroidectomy *per se* produces at once a profound disturbance in the medulla, we see

no difficulty in regarding this phenomenon of hyperæmia as due to such an effect alone, the medulla being all the more susceptible in these patients from the long-continued effects of this disease. At the same time this high rate of mortality, evidently dependent upon the operation itself, certainly should weigh against its performance so long as other remedial measures can be adopted.

## KELOID TUMORS OF THE EXTERNAL EAR.\*

By WILLIAM SCHEPPEGRELL, A. M., M. D.,

NEW ORLEANS,  
VICE-PRESIDENT OF  
THE AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY;  
CHAIRMAN OF THE SECTION IN OTOTOLOGY, LARYNGOLOGY, AND RHINOLOGY,  
LOUISIANA STATE MEDICAL SOCIETY;  
VICE-PRESIDENT OF THE NEW ORLEANS ELECTRIC SOCIETY;  
FELLOW OF THE  
SOCIÉTÉ FRANÇAISE D'OTOLOGIE, DE LARYNGOLOGIE ET DE RHINOLOGIE, ETC.

AMONG the non-malignant tumors of the auricle, the most common is the keloid, a fibroid neoplasm developing from the cicatricial tissue of the pierced lobule. As the piercing of the ear for rings is a relic of barbarism chiefly restricted to women, we find this form of tumor limited almost exclusively to this sex.

Keloids occur more frequently in the negro race, as shown in the statistics on the Comparative Pathology of Diseases of the Ear, Nose, and Throat in the Negro, which I read recently before the Parish Medical Society. This statement is also supported by Saint-Vel (1), Knapp (2), Turnbull (3), and others, who maintain that it is due to the large size of the ornaments which negroes wear in the ear.

The opinion of the writer, however, is that the keloid, so frequently found in the negro, is not due so much to the size or nature of the rings worn in the ear, as to the inherent tendency of this race to the formation of fibroid tumors. This fact is substantiated by the experience of gynecologists, who find the fibroid tumors of the uterus a most common occurrence in this race.

Fibroid tumors, although usually found on the lobule, may also develop in other parts of the auricle, as one case reported by Burkner (4), in which a hard, elastic tumor of spherical shape filled out the whole concha of a fifteen-year-old boy.

Politzer (5), in referring to keloid tumors of the auricle, states that "they usually do not recur." My experience with this class of tumors has not led me to form this opinion; on the contrary, unless the greatest care is exercised that the pathological formation is entirely removed and that a minimum of cicatricial tissue is left from the operation, the tendency to recurrence is very great.

Turnbull (3) believes that the formation of keloids is due to some peculiar condition of the system, chiefly scrofulous, or some galvanic action of the mixed metal employed in the manufacture of the jewelry which is

sold for pure gold. He maintains that he is supported in this opinion by the number of such tumors that occur, not in the true negro, but in persons of the mixed blood of the white and black, who are more liable to scrofulous diseases than the true negro.

Referring again to the statistics which I collated on the Comparative Pathology of the Negro (6), we find that out of 11,855 cases of diseases of the nose, throat, and ear, there were eight cases of keloid tumors of the lobule of the ear; of this number seven were in blacks, one was in a white person, and one was in a mulattress. In my own experience, both in hospital and private practice, I have seen fourteen cases of these tumors, of which two were white, ten negroes, and only two mulattoes.

From these statistics, and from the reports of Turnbull (3), Schwartz (7), and other writers, we are supported in the statement that the keloid tumor of the ear is found more frequently in the negro race and but rarely in the white; and where it is found in the mulatto, it is due, not to a scrofulous condition, but to that inherent tendency to the formation of fibroids inherited from the negro parentage.

These tumors are very frequently bilateral, ten of the cases referred to being observed in both ears. The keloids in the whites were of small size and unilateral; in the mulatto, one was bilateral, while of the ten cases in the negro, nine were bilateral.

As regards the statement made by various writers that the cause of these neoplasms is the irritation from impure metals, if this were the only ætiological factor these tumors would be much more common in the whites, for, in the lower order of these, the same impure metal, straw, and threads are used in the pierced lobule as in the negroes.

Knapp (8), in *Archives of Otolaryngology*, volume iv, states that "a recurrence of these tumors is mainly due to their incomplete removal." In one of his cases in which a portion of the tumor was left, so as to make a better flap, recurrence soon took place, but a second and thorough removal of the growth was not followed by any further development of the tumor.

The avoidance of a recurrence not only requires the complete removal of the pathological tissue, but also the avoidance, as far as is practicable, of cicatricial tissue after the operation. In a number of cases which I have seen operated upon the tumor was radically removed, the base of the wound cauterized, and the wound allowed to heal by granulation. In each of these cases recurrence promptly took place in the cicatricial tissue, just as the original tumor had developed from the original scar of the punctured lobule. My practice has been to carefully dissect out the tumor, after anesthetizing the part by injecting five to ten minims of a four-per-cent. solution of cocaine hydrochloride, and close the wound entirely, if necessary by a plastic operation, and allow the wound to heal by first intention. In ten cases of operation by this method, recurrence took place in

\* Read before the Section in Laryngology, etc., of the American Medical Association, May 8, 1896.

only one, and in this case healing by first intention was prevented by the patient scratching the ear and tearing one of the stitches. A second operation in this case was followed by a permanent cure.

Fibroid tumors may develop without piercing of the ear, as in a case reported by Holt (9), in which a fibroid tumor developed in a lobule which had never been pierced. Klebs (10) also reports a case of a nine-year-old boy, in which a keloid developed on the posterior margin of the auricle after an injury of the ear. Fibroid tumors are also rarely found in the concha, a case having been observed by Anton (11).

The size of these tumors varies from a slight hypertrophy of the cicatrix to tumors of considerable size. In one case of operation at the Eye, Ear, Nose, and Throat Hospital the growth had attained the size of a fowl's egg. The presence of these tumors usually gives rise to no pain, but they are somewhat inconvenient on account of their large size. Their removal is generally demanded by the patient for cosmetic purposes.

As already stated, to prevent a recurrence it is necessary not only to remove the tumor in its entirety, but to so complete the operation that the wound will heal by first intention with the least possible amount of scarring.

Burkner (12) states that "when a tumor is very small it may be excised and its site destroyed by electrocautery or by nitrate of silver." As the result of this operation would be the formation of cicatricial tissue, I do not consider it advisable, but prefer to excise a small section of the lobule, including the tumor, and close the opening by means of stitches; the result of this operation is usually satisfactory and the deformity but slight.

The following is a history of two representative cases of keloids of the auricle which I have selected from my case book:

**CASE I.**—Mary E., black, aged fifteen years, applied to the Eye, Ear, Nose, and Throat Hospital, June 10, 1894, with keloid tumors of both auricles. She gave the following history:

Three years ago she had an attack of typhoid fever which lasted one month. No history of any tuberculous or specific diseases, and the patient appears in good physical condition. Two years ago she had her ears pierced with a needle, a straw being placed in the openings to prevent them from closing. The ear around the punctures became sore and inflamed and enlarged to the size of a hen's egg. In three weeks the swelling had subsided, but she then observed a small lump on the ears where the punctures had been made; these lumps continued to grow for two years, but gave rise to no pain.

The patient desired to have them "cured" because they were unsightly, and because she feared they would develop into "cancer." An examination showed a well-developed keloid of each ear lobule, the tumor on the left ear being nineteen millimetres in diameter and limited to the lobule; the neoplasm on the right side, however, was much larger (Fig. 1), being forty-two millimetres in diameter and involving not only the lobule

but also a considerable portion of the posterior inferior part of the pinna.

On June 15th the smaller tumor was excised, after injecting a four-per-cent. solution of cocaine muriate,

FIG. 1.—Case I.

and the wound carefully closed with silk stitches. Five days afterward the stitches were removed and eight days afterward the parts were completely well, having healed by first intention; the deformity was scarcely noticeable. A week later I operated on the right side, removing all the growth and also a considerable part of the cartilage of the auricle, which was involved; the wound was then carefully closed by interrupted stitches. A local injection of a four-per-cent. solution of cocaine acted excellently in this case, as there was no pain at any time during the operation. Six days afterward the stitches were removed and the wound healed *per primum*, there being no suppuration at any time. The weights of these keloids were seventy-eight grains and a hundred and sixty-two grains respectively. Six months after the operation there had been no recurrence.

FIG. 2.—Case I after operation.

**CASE II.**—Alice B., black, aged twenty-two years, had keloid tumors of both auricles (Fig. 3). Two years

ago the ears were pierced with a sewing needle, the wound healing without giving rise to any pain or swelling. One year afterward she noticed a slight swelling at

FIG. 3. CASE 2.

the side of the puncture of the right ear and shortly afterward also of the left ear. These tumors gradually increased in size until the tumor on the left ear was nine millimetres, and of the right ear twenty-nine millimetres in diameter. These tumors were removed under cocaine anaesthesia, the edges of the wound approximated and carefully closed by stitches, as in the last-described case, both ears healing by first intention. Fourteen months afterward there had been no reappearance of the growth.

**The Staphylococcus Pyogenes in Acute and Chronic Otitis Media, and their Treatment.**—Pes and Gradenigo (*Ann. des mal. de l'oreille et du larynx*, July, 1895) draw the following conclusions from their observations: In general, the primary and secondary infections of the middle ear are of nasopharyngeal origin. Very rarely the secondary infections come from the external auditory canal through the perforation in the tympanic membrane. The main feature of the treatment is the use of antiseptic occlusion of the canal by cotton.

## AN APPARENT CRYSTALLIZATION OF EOSINOPHILE GRANULATIONS.

By ARTHUR J. PATEK, A. B., M. D.,  
MILWAUKEE, WIS.

OF the various forms the eosinophile granulations may assume, the following are described:

1. Granules and globules of varying size.
2. Ovoid granulations.
3. Rod-shaped form (cylindro-crystalloid of Ehrlich), which may exist together with or without globules in the cell.

It has been shown experimentally that out of the contents of pemphigus vesicles, so rich in eosinophile cells (though, according to a recent report in *La Semaine médicale*, June 17, 1896, the vesicles in dermatitis herpetiformis are by far richer in them), the Charcot-Leyden crystals can be obtained in abundance by the action of cold. What relation, if any, there exists between these crystals and eosinophile cells is not positively known, though it is suspected by some that the crystals may arise from the latter.

Eosin-haematoxylin. Zeiss,  $\beta$ , immersion,  $\times 1,000$ .

I wish now to call attention to a new crystal form, to my knowledge as yet undescribed, which I recently found in a blood preparation made from an individual suffering from a suppurative axillary adenitis. A slight leucocytosis (multinuclear) existed in this case, but disappeared with the disappearance of the adenitis.

There are quite a large number of ruptured leucocytes in this specimen, the rupture probably arising in the act of forcibly separating the two cover slips after the drop of blood had spread evenly and in a thin layer between them. Therefore the crystallization of the granules must have taken place immediately after the separation

of the cover glasses and probably before their fixation (by heat).

It (to me) seems so evident, from the appearance of the crystals and their relation to the cell, that they are a product of the granules of the latter, that I hardly question the correctness of my conclusion.

The eosinophilous property of the crystals—unfortunately not shown in the accompanying diagram—is marked, for they possess the same pigmentation as the granules in the cell. We may distinguish several varieties of the eosinophilous bodies:

1. The granules and globules of varying size within the cell and in different parts of the field.

2. The rod-shaped form, cylindro-crystalloid, also within the cell and in the field.

3. This new variety, which, from its resemblance to bundles of grain, might be called the "sheaf form" of eosinophilous crystals.

These crystals have, of course, no special significance, and are of mechanico-chemical origin. Though I have, since obtaining this specimen, looked for them in many other blood preparations, I have been unable to discover any.

It is possible that what I take to be a hitherto undescribed form of eosinophile crystallization may be a known crystal of other origin than that to which I attribute it; but from the fact that it bears no resemblance to any known form of crystals that are found in or obtained from the blood (hæmatoidin, Charcot-Leyden, and the various forms of hæmin crystals), and that its pigmentation quality (strongly eosinophilous) is identical with that of the granules in the cell from which it seems to have sprung, and from its peculiar relation to the ruptured eosinophile cell, I think the view that these crystals are transformed eosinophile granulations justified.

I can hardly entertain as a possibility the view that they are an element foreign to the blood and artificially introduced.

I shall be glad to receive information on this subject.

117 WISCONSIN STREET.

## THE FUNCTIONAL VALUE OF CORTICAL CEREBRAL MOTOR CENTRES IN DIFFERENT ANIMALS.\*

By WESLEY MILLS, M. A., M. D., ETC.

PROFESSOR OF PHYSIOLOGY IN MCGILL UNIVERSITY, MONTREAL.

It is impossible to excite in the pigeon any of the ordinary movements of the limbs or trunk by electrical stimulation. This I have established by a long series of experiments. The same applies to the domestic fowl,

and probably to all or nearly all birds, though it would be interesting to know whether it holds for the parrot with its remarkable handlike motor power. On removal of the entire cerebral cortex in the pigeon, nearly all the movements of which the intact bird is at any time capable can still be called forth, though none of them are now voluntary. This seems to indicate that the mechanism necessary for executing such movements exists somewhere else than in the cerebral cortex, presumably chiefly in the subcortical centres of the cerebrum, or, at all events, in the encephalon somewhere.

We have found that cats from which we had removed at one operation both the areas around the crucial sulcus (which corresponds fairly well functionally with the fissure of Rolando), and in which the centres for the head and limbs lie, can walk in some fashion as soon as they recover from the anæsthetic, and they gradually move better and better, so that even within the few days that they survive this operation they have to a considerable degree recovered their ordinary gait. Our cats thus operated on refused food entirely, and notwithstanding some forced feeding, which was not very satisfactory, died in a few days.

But cats from which the same areas were removed within a few days by successive operations did well, and, to ordinary observation, walked within even three or four days afterward as though their brains were intact.

The kitten I show you to-day could also "wash its face" with both paws as well as any cat on the fourth day after the removal of the second motor region referred to above.

In dogs the recovery is slower, in my experience, but nevertheless occurs to a large extent.

The rabbit can walk after removal of the greater part of the entire cerebral cortex, and the hind legs seem almost unaffected at any time.

After operations of a similar though less grave character on the monkey there is decided paralysis from which there may be slow recovery. The same seems to be the course of events following surgical removal of parts of the motor area in man; but in his case, and sometimes in the monkey, the paralysis is very lasting.

I could demonstrate to you, did time permit, that in the rabbit, cat, and dog the different areas (centres) of the cerebral cortex are not on the same functional plane. It is evident, from contrasting these animals—especially if we include the bird—with the monkey and with man that the expression "motor centres" should convey a very different meaning according as we speak of one or the other.

Had this been realized earlier, the controversies that have raged over cortical localization would have at least been of a less heated character. It is to my own mind clear, after considerable investigation of this subject on a variety of animals, that we must recognize that localization exists in varying degrees in different animals, and also that cortical centres are very differently organized.

\* This paper, accompanied by demonstrations, was read before the Canada Medical Association in Montreal, August 27, 1896. Dr. J. W. Scane, demonstrator of physiology in McGill University, assisted in the required operative procedure, etc.

In the bird there are none of the ordinary cortical motor centres at all, if one can settle such a question by electrical excitation.

In all the other animals referred to in this paper the writer has found that:

1. Certain areas of the cerebral cortex respond to electrical excitation by movements.

2. Certain areas have a different though analogous distribution in different animals.

3. These movements are more readily excited, are more elaborate, and their centres are less readily exhausted in some animals than in others.

4. The exact location of the motor centres is better defined the higher we ascend in the animal scale.

In all the foregoing there are variations for individuals.

To put the whole matter briefly, we must recognize in different animals (and to some extent in different individuals) all degrees of functional cortical development; and it is further capable of demonstration that all centres in the same animal are not equally well organized, or, in other words, are not on the same physiological plane. In the rabbit, for example, the centres for the facial movements and those of the fore limb are better developed than others, and in the dog and the cat the centres for the fore limbs are better organized than those for the ears or tail; and the same applies throughout.

We may draw a curve to express these facts and place the different groups of animals in their physiological order thus:

This is further evident, as I have elsewhere shown, by tracing the functional development of the cerebral cortex in the young of the rabbit, guinea-pig, rat, mouse, cat, and dog.

There is a time when no reasonable strength of current will, when applied to the cortex, give rise to movements in those animals which are born blind, but later, and in a regular order, the centres are developed.

Such a conception of motor centres is in harmony with the facts of clinical medicine. It is well known that all movements in man are not equally readily abolished by cerebral disease or equally readily restored.

Do not such facts as these demonstrations impress on us make the relative part played by higher and lower centres plainer in man as well as in the lower animals?

Evidently, cortical centres are relatively more important in man; but the view that even in man they can not be replaced by others to some extent seems to me to lack foundation either in physiological experiment or in clinical medicine.

The case resolves itself into a difference in degree as concerns man and the lower animals, and to make in some measure this great truth evident has been the main purpose of these demonstrations.

*Demonstrations.*—The principles stated above were illustrated by demonstrations on the pigeon, the rabbit, the cat, and the dog.

A pigeon from which the entire cerebrum had been removed an hour before was shown to be capable of flight when thrown into the air.

A rabbit, with ablation of the motor centres for the limbs and the neck on both sides, on the day previous, by a single operation, was able to jump vigorously, only the merest tendency to slipping of the fore paws on a smooth surface being noticeable.

A mature cat that had been the subject of operation about the middle of June—the area around the right crucial sulcus having been excised—appeared to move and act in all respects like a normal cat. More remarkable still was the case of a kitten a few months old. About five weeks ago the cortical centres for the limbs and neck on one side were excised, and two weeks since the same operation was done on the opposite side. It was difficult to distinguish in the movements of this kitten any difference from those of a normal cat. Its intelligence seemed to be little if at all altered. It walked, ran, washed its face, etc., to all intents and purposes like any other cat under ordinary circumstances.

A puppy three months old had the circumcrucial motor area (for neck, arm, and leg) removed about a week before. It could walk, run, scratch with its hind legs, etc., though there was a tendency to slip, and at times a bending under of the paw on the side opposite to the lesion. This is somewhat analogous to wrist-drop in the human subject.

The puppy was rapidly recovering, though at present he illustrated a condition that, in a somewhat more marked degree, immediately follows operation in the cat also, and to a lesser extent in the rabbit. It should not be termed paralysis.

The two areas that had been removed from the kitten, and the single one from the puppy, were exhibited. It was perfectly plain from these demonstrations that cortical "motor centres" had not the same signification, relations, etc., in these animals as in the monkey and in man.

All the operations were performed under an anæsthetic, and the wounds healed rapidly.

It should also be pointed out that in each instance the motor areas were determined by electrical stimulation of the cortex with the rapidly interrupted current of a Du Bois inductorium.

These demonstrations in themselves warrant the cautions expressed in regard to theories of localization in my *Text-book of Physiology*\* at the date of its publication, and I am as firmly convinced as ever that it is only by the comparative method that broad, sound, and enduring laws can be established in this or any other department of physiology, on which human and comparative medicine must each alike rest.

## THE CLINICAL VALUE OF ANTISEPTICS, BOTH INTERNAL AND EXTERNAL.

By HOWARD LILIENTHAL, M. D.

EVERY discussion should begin with a distinct understanding of the terms used to express the subject in hand.

While the term antiseptics in its broad sense refers to antiputrefactive agents and methods, it may, for the purposes of this paper, be defined as means for checking certain morbid processes by destroying the micro-organisms which cause them or by lessening the virulence of these micro-organisms. This definition includes physical as well as chemical antiseptics.

By the use of internal antiseptics we strive to accomplish the desired object from within the organism itself, administering the remedy in such a way that it may enter the economy. The true internal antiseptic should act after its actual entrance into the system. A substance given by mouth for the disinfection of the alimentary tract by direct action on the microbes therein contained can not strictly be called an internal antiseptic, while the administration by mouth of quinine for the modification of the virulence of the plasmodium malarie contained in the blood exemplifies the use of a true internal antiseptic.

External antiseptics must act upon the germs without first entering the economy. As an example of this class we have the application of germicide substances to infected wounded surfaces.

The clinical value of antiseptics is inversely proportionate to their power to harm the host, for it would be unreasonable to employ means for the destruction of germs which, however successful, should also destroy our patient.

All antiseptics may be divided into two great classes, the physical and the chemical. The physical class consists of subdivisions which include radiant energy—*e. g.*, heat and mechanical means. As an example of radiant energy may be cited the thermo-cautery, while the surgical draining of septic abscesses belongs under the head of antiseptics by mechanical means.

Chemical antiseptics are elementary substances or their combinations—such, for example, as chlorine, carbolic acid, and bichloride of mercury.

The discussion of the clinical value of the various forms of antiseptics will now be taken up in order.

*Internal Antiseptics.*—1. The living animal organism has an inherent antiseptic power or quality. That this exists can not be doubted when we become aware of the fact that we are in constant contact with great numbers of pathogenic germs, yet that only occasionally are we attacked in such a way as to disturb the balance of health; and this in spite of the fact that our normal body temperature is one at which most germs thrive. In the event of death by violence, even when no microbic disease previously existed, putrefaction will at once set in.

The antiseptic power of various tissues has been investigated, and the result seems to justify the assumption that living tissue has a certain degree of germicidal power, and that the leucocytes are probably in this respect the most active elements.

2. In the belief that in the cell nucleus would be found the active antiseptic principle of the living tissues, various preparations, embodying the whole or a part of this portion of the cells, have been artificially produced. These preparations of cell nuclei have been shown to be of some value in combating certain germ diseases—such, for example, as tuberculosis.

(Those drugs which act upon septic disease by causing an increase in the number of white blood-cells will not be discussed, because the white blood-cells do the antiseptic work and not the drug.)

3. The elevation of the body temperature, which accompanies many diseases caused by germs, may reach such a degree as to inhibit the growth of these very organisms. It may therefore be questioned whether a simple lowering of the temperature by means of antipyretics is wise, especially in cases where the pyrexia is well borne. It is said, for example, that the high fever accompanying erysipelas decidedly checks the growth of the streptococcus, and it is a commonly observed fact that high fever in the course of a gonorrhoea is almost always accompanied by a diminution of the urethral discharge and of the number of gonococci present.

4. Certain products of bacterial cultures are found to be poisonous to the very germs which produce them. All through the various kingdoms of living things, whether plant or animal, it is found that excreta are poisonous in their action upon the organisms whence they come. Taking advantage of this law, Koch sought to destroy tubercle bacilli in the human being by means of hypodermic injections of tuberculin, a product of the bacilli themselves. This was only partially successful, and its therapeutic use had to be in large measure abandoned because of the many untoward effects produced in addition to those desired.

Working on the same lines, however, substances have been produced which have a most decided internal antiseptic effect in cases of diphtheria and in certain cases of septicæmia. At the present writing, work in

\* *A Text-book of Animal Physiology.* D. Appleton & Co., New York, 1889.

this direction is being rapidly pushed, and there is reason to believe that internal antiseptics by bacterial products will in future be a most valuable aid to medicine.

Some diseases not actually proved to be of microbic origin, but for good reason believed to belong to this class, have been cured by the introduction into the system of substances derived from the organs of animals which have been afflicted with the same malady. Usually the organ which seems to be the seat of the trouble is that selected for use in preparing the remedy. The antirabic inoculations first used by Pasteur belong in this category, and may safely be placed among the valuable internal antiseptics.

Preventive inoculation may be regarded as antiseptic, because it causes the destruction of such germs as may enter the organism even before they cause actual symptoms of poisoning.

5. We now come to the group of antiseptic chemicals of known composition. Some of these are so sure in their action that they may be regarded as specifics—for example, the various preparations of mercury in the treatment of syphilis. The drug acts no matter how it enters the organism, whether by inunction, inhalation, subcutaneous injection, or by absorption from the alimentary canal. By regulating the dose of toxic effects of the mercury may be almost or entirely avoided. The fact that mercury has such a certain effect in modifying the course of syphilis is in itself sufficient to establish the great value of internal antiseptics. The pity is that we know so few drugs whose action is so prompt and sure. Quinine in malarial disease is almost equally effective, but beside these two examples of true internal antiseptics all others sink into insignificance. The internal administration of bichloride of mercury in other diseases of a septic nature has been tried, but with doubtful, or at most very variable success. The drugs of the phenol group have also been extensively used, especially in tubercular disease, and they have in many cases seemed to affect favorably the course of the malady, but it has not been satisfactorily determined, whether because of their antiseptic qualities or on account of their physiological action on the patient.

The balsams, aromatic oils, and salicylates have shown themselves to be of considerable use in checking fermentation, especially alkaline fermentation, in the urinary tract. A simple experiment will show their antiseptic action. Let an individual pass urine and place the vessel in a warm room. Immediately after he has urinated administer ten drops of wintergreen oil (*ol. gaultheriæ*), and in two hours let him urinate into another vessel, placing it beside the first. The first specimen will be putrid in a few hours, and the microscope will show myriads of bacteria, while the second will remain sweet, and even in from three to six days only a few germs will be found in the specimen.

This class of drugs has also some clinical value when given internally in certain constitutional disturbances

of a septic nature, where they are believed to act as germ destroyers. The discharge and irritative symptoms of gonorrhœa, for example, are much modified under their influence, while gonorrhœal rheumatism and some forms of true pyæmia are lessened in virulence. Whether or not true rheumatism is a germ disease, its course is surely modified by these chemicals, notably by the salicylates and the oil of gaultheria.

6. The next class of antiseptics which demands our attention belongs in the strictest sense to the external group, though the substances are given by mouth and act inside the body, not, however, after absorption into the system. I refer to antiseptics of the alimentary tract, the gastric and the intestinal. Antiseptics of the mouth are still more strictly external.

Our most efficient means for combating germ infection in the stomach and its contents is by washing or lavage through a rubber tube made for the purpose. When the fermentation is acid, the best results will be attained by the use of an alkaline wash, which should always be preceded by a thorough mechanical irrigation with warm water. This irrigation should be continued until the water returns clear, and then the alkaline antiseptic fluid should be poured in and allowed to remain for a variable length of time, according to the individual case. Where alkaline fermentation exists, the best results from irrigation will be attained if one of the true antiseptic drugs in mild dilution be used. Peppermint water or a very mild formaldehyde solution may be employed with benefit.

Drugs like calomel, which draw water from the walls of the viscera (hydragogues), and at the same time cause an increase of peristalsis, act as mechanical antiseptics, and their effect is practically an irrigation of the alimentary canal. In the case of calomel, a certain amount of bichloride of mercury is also formed, so the irrigation becomes a chemically antiseptic one as well. The usual purging salines often do excellent work in causing a drainage of the bowels which is thoroughly antiseptic in its action and accounts for the good results following the saline treatment in septic enteritis, where Nature usually points the way by causing a diarrhœa from the irritation by the products of putrefaction.

The attempt has been often made to disinfect the alimentary tract or a portion of it by converting its contents into a germicidal fluid. For this purpose aromatics have been used and also chemical compounds, which, becoming decomposed in the intestine, liberate an antiseptic in the very place where it will do the most good. Later study and research has not borne out the rather enthusiastic statements of the earlier experimenters. In the case of the aromatics, to be sure, the odor of the stools has sometimes disappeared or has been masked, but clinically the progress of disease has been but little changed, and it is becoming more and more apparent that drugs which act by mechanical purging are the surest and the least dangerous.

*External Antiseptics.*—7. The true external antiseptics of modern surgery have been used understandingly for a much longer time than internal antiseptics. The clinical value of surgical antiseptics is incalculable. Here, as in all other branches of the subject, we understand the term in its broad sense, and we recognize the incision and drainage of an abscess as an antiseptic procedure quite in the same light as the employment locally of a chemical substance.

It is possible in surgical work to carry out the technique of antiseptics far more accurately than it can be done in the other branches of medicine, and on scrupulous attention to detail depends clinical success. The accuracy and consequent efficiency of our methods varies considerably according to the anatomical region involved and our ability to disinfect it. It will therefore be well to discuss briefly surgical antiseptics in general, and then to apply the principles to various regions of the body. Let us describe the management of a cutting operation upon a non-infected part of the body—such, for example, as the excision of a lipoma of the shoulder. Here it is our wish to perform an absolutely clean or aseptic operation, and to insure this condition and its continuance throughout the operation all our watchfulness and skill must be brought into play. First we must get rid of all the germs which exist upon this region of the skin of our patient. This is done by shaving the part and its surroundings, then by scrubbing with green soap and hot water, followed by a brisk rubbing with a clean towel soaked in alcohol or ether, to remove the soap and remaining traces of fat. A strong but not too irritating chemical antiseptic, such as bichloride of mercury in 1-to-500 solution, is now poured or sponged over the skin and completes the preparation. All surrounding non-disinfected parts must be covered with clean towels or other cloths so that accidental contact of dirty with clean regions shall be impossible.

The hands and arms of operator and assistants should be scrubbed with green soap for five minutes, then scrubbed in strong alcohol, and finally immersed for two minutes in 1-to-1,000 bichloride, or an antiseptic of similar strength. All persons assisting in the operation should wear sterile gowns over their clothing so that accidental contact of hands or instruments with the undisinfected clothing may be avoided. An aseptic cap or a clean towel should cover the head.

The instruments for use during the operation must have been freshly boiled in water, to each quart of which has been added a heaping tablespoonful of washing soda.

Gauze or cotton pads, sterilized by dry heat, may be used instead of sponges; or if sponges are preferred, they must be carefully cleaned and rendered aseptic by mechanical means and subsequent prolonged soaking in strong antiseptic solutions.

Ligatures and sutures of silk, cotton, or silkworm gut should be boiled well in an antiseptic solution of

efficient concentration, but not so concentrated as to weaken the tensile strength of the material.

Catgut may be sterilized by boiling in alcohol or by soaking it for an hour in a ten-per-cent. alcoholic solution of carbolic acid. The catgut may then be kept for use in absolute alcohol.

The room where the operation is to take place should be disturbed as little as possible beforehand. Carpets should not be taken up, and no sweeping or dusting should be permitted for fear of the flying germ-laden dust.

When the operation is finished and the absorbent sterile dressing has been applied, then comes the test of the thoroughness of our work, for where no germ has entered there the wound will heal without hindrance and under one dressing.

This, then, represents the value of antiseptic methods in a "clean" or aseptic surgical operation upon the person of a healthy individual. If, however, the operation itself is one which is performed as an antiseptic measure, the steps are the same as those just described, provided every particle of infected tissue can be removed. When this is not possible the wound must be left open and dressed "wet" with material soaked in a mild germicidal solution which shall act chemically upon the microbes, and the whole dressing must be covered with a waterproof layer—oil silk or gutta-percha tissue. This wet dressing will promote the perfect draining away of septic secretions. Drainage is the best antiseptic where the whole infected tissue can not be at once removed.

Modified procedures may be useful in operations upon special regions. The conjunctival sac, the nose, the mouth, the urethra, and the vagina are lined with mucous membrane. A true mechanical disinfection is here impossible, and powerful or acrid germicides too energetically applied may cause a congestion with swelling and the secretion of abnormal mucus, a condition which invites infection. Very frequent mechanical cleaning, say once an hour, with mild chemical antiseptics, is our best preparation. The washings should be continued from twelve to twenty-four hours before the operation.

The rectum should be cleaned incidentally by purgation through the alimentary tract, and this should be followed by enemata. At the time of the operation the mucous membrane may be well scrubbed with soap on a sponge. Primary union, after careful work, is the rule in this region as in others.

The bladder may be cleaned by antiseptic washings or irrigations, but here as elsewhere drainage is of the utmost value. Indeed, very many cases of cystitis may be cured without washing by simply catheterizing every three hours, day and night, to get rid of all residual urine. The writer has many times proved the usefulness of this antiseptic measure.

An important and valuable procedure may here be mentioned. I refer to the method of preventing the

extension of local infection in the serous cavities by using gauze pads or strips to wall off healthy structures from those which are diseased. Large collections of pus in the abdominal cavity may be safely evacuated after protecting the surrounding parts by means of these gauze barriers. Peritonitis need not occur if this work has been carefully done.

In some diseases requiring surgical intervention we have to deal with germs of great virulence, and there may be danger from their entrance into the blood current when incision is made. Malignant pustule is an example. The accident may be avoided by the use of our most powerful antiseptic—heat—in performing the operation. A piece of metal, kept red-hot by an electric current or by a stream of benzine vapor, may be used to burn the inflamed tissues deeply, or, indeed, to destroy them entirely.

Absence of heat (cold) is often of value as an antiseptic. The temperature of a small part of the body may be lowered many degrees, and may be kept in this condition for days at a time by the continued application of cold. As an external antiseptic, where we do not wish for the destruction of tissue, cold is a more powerful agent than heat. The local temperature may be raised but a few degrees, it can be lowered many. The germs may not be killed by the action of cold, but they will be often prevented from multiplying, so that the patient may become stronger and his body cells may be enabled to resist their attack.

In this paper I have striven to show the clinical—*i. e.*, the practical and true value of antiseptics. I have tried to show that the word means more than carbolic acid or iodoform; that although artificial compounds intended to kill germs may be useful assistants, they are seldom, if ever, indispensable.

It may not be amiss to examine briefly the advances made in the treatment of some typical morbid conditions, as shown by the results obtained from antiseptic methods of attack and defense. By attack I refer to the active treatment of the existing disease, and by defense I mean prophylaxis, which guards the healthy being from harm.

Internal antiseptic treatment, as the writer has already said, is best exemplified by the mercurial remedy for syphilis. This terrible disease has for civilized persons lost nine tenths of its horrors, because even if the malady is not literally "cured" its course may with great certainty be so modified that the hideous pictures of deformity and untimely death are rarely encountered, except in cases where ignorance or carelessness have led to neglect. Instead of the frightful deformity and the tedious and uncertain dosing with nauseous drugs, the patient, though still unfortunate, may at least avoid public exposure, and may attend to his usual occupations while the treatment goes on.

Gastro-intestinal antiseptics have shown itself of immense value in the treatment of the septic diarrheas of

children. In the old days the deaths from this source were simply appalling. Constipation, for a day or two, usually unnoticed, gave an opportunity for toxic fermentation. Then came the elevation of temperature, also often unnoticed, and finally the convulsion and the diarrhœa, with death a few hours later, ending the dreadful scene.

In the antiseptic, or, as it is often called, the surgical treatment of the trouble, we heed the first notes of warning. A hydragogue purge, frequent irrigations of the colon, and the withholding for a day or two of the fermenting food (usually milk) will, in the vast majority of instances, suffice to establish normal conditions with rapid convalescence. The children of the poor or of the ignorant—the combination is, alas! too common—are the ones who in these days form the great bulk of those who succumb to this scourge of innocent childhood.

Prophylaxis by isolation and by the sterilization of excreta and of infected garments has saved millions of lives by stopping the spread of such diseases as Asiatic cholera and typhus fever, while these precautions, together with preventive inoculations (vaccination), have almost stamped out small-pox as an epidemic.

The recognition of the microbic character of tuberculosis is the cause of the first truly intelligent treatment of this sickness, whether its manifestations are general or local. Instead of the hopeless death sentence of "change of climate," we now have, especially in incipient cases, a very fair chance that the course of the morbid process may be modified, or even that a permanent cure may result. This wonder may be accomplished by careful local and constitutional treatment. Recognizing that leucocytosis is a great power for good in this disease, we try to bring the condition about preferably without drugs, but physiologically by means of very frequent feeding. An hour or two after a meal the number of active leucocytes in the blood has been found to be much increased. By feeding often—as, for example, by giving a glass of hot milk every hour—we may induce a constant state of leucocytosis, thus availing ourselves of the internal antiseptic principle of the body referred to above under *Internal Antiseptics, 1*.

The site of local tuberculous infection, whether pulmonary or otherwise, we now treat on surgical principles. This does not necessarily mean that we operate, but that we make use of rest to the inflamed parts, and that we employ dry cold (ice bag) to retard the development of the germs, with consequent destruction of tissue. The result is that very often the case does not go beyond the first stage and ulceration or abscess is avoided, the disease, whether in bone, lung, or other tissue, becoming encapsulated. It is a noteworthy fact that in direct proportion to the difficulty experienced in applying these antiseptic principles the disease is or is not amenable to treatment. Thus, the joints and bones may be very successfully treated by fixation and cold, while the disease in the lungs is much more difficult of attack,

and tuberculosis of the larynx and of the membranous brain coverings is still almost hopeless.

In the days when tuberculosis of bone and joint was not understood the rule of treatment was expectant, and the poultice was often employed to actually encourage the formation of abscess which might later be "lanced" when on the point of bursting. The resulting sinuses were seldom interfered with, and joint resections were deservedly rare because erysipelas, gangrene, or pyæmia too often necessitated amputation, or actually ended the case by killing the patient. Serious infection after such operations is at present very infrequent, and the rule is rapid and uneventful recovery.

Surgery in general has become a scientific possibility solely on account of antiseptics. The youngest hospital graduate in 1896 will successfully accomplish cures by operation which a hundred years ago would have been rightly accounted examples of criminal recklessness.

It has been said that the comparative safety of operative procedures has caused an alarming increase in their frequency.

By a critical reference to hospital reports we do find that the number of operations has enormously increased, but if we look over the character of the work done we find that destructive and maiming surgery is becoming more and more rare, while conservative and reparative operations are very largely on the increase. Old statistics as to the dangers of any given operation are now ridiculously unreliable. Erysipelas and hospital gangrene are seldom encountered in well-managed institutions, hospital gangrene, in fact, having been practically exterminated.

Life-saving operations upon the viscera, now of daily occurrence, were formerly most infrequent sights, and were practically limited to accidental wounds involving the body cavities, and to emergencies with a plainly visible cause, as, for example, strangulated hernia. Instead of operations for appendicitis, with a large percentage of recoveries, we heard of deaths from "inflammation of the bowels."

Long before the germ theory of disease was understood there were men who, in the face of unbelief and ridicule, recognized contagion as the cause of certain forms of surgical fever. Among the first to know the principle of septic infection and with his mighty pen to spread broadcast his wisdom, was Dr. Oliver Wendell Holmes, who, in an essay on the contagiousness of pyæmic fever, most powerfully set forth the truth. Although the actual cause of this dread disorder was not known to him, his rule for prophylaxis by forbidding an infected nurse or physician to visit a lying-in woman is like a milestone in the march of medical science.

True antiseptics, internal and external, have long been blindly sought. Indeed, most of the early advances in the treatment of disease now known to be of microbic origin have been unwittingly on antiseptic

lines though usually the result of happy accident. The years are few, indeed, since the true light has shone upon us, but it has brightened the dark paths where once we groped, and points with steady beam the road to progress.

#### METHODS OF DIAGNOSTICATING DISEASES OF THE ANTRUM OF HIGHMORE, AND THEIR TREATMENT.\*

By FRANK S. MILBURY, M.D.,

LARYNGOLOGIST, ETC., TO THE BEDFORD DISPENSARY AND HOSPITAL,  
BROOKLYN.

In my opinion too little attention is given to this cavity in connection with affections of the nose. Disease often exists in this sinus when no visible indications are present.

Lennox Browne says that he has always found empyema of this antrum when suspected, probably only having operated on patients where disease had so far advanced as to make diagnosis almost certain.

Lichtwitz, of Bordeaux, recommends irrigation by puncture with a straight trocar through the inferior meatus. When the diagnosis of empyema is a little uncertain, this, he says, in all cases, clears it up conclusively. In 167 punctures already made, 54 gave positive results, while in 113 the antiseptic solution returned clear. But, in my opinion, this is not by any means a positive diagnosis, as always more or less blood is present, making it impossible to tell whether there is pus or not, unless in large quantities.

In many cases, even under a local anæsthetic, the pain is considerable, and patients complain of what they think unnecessary suffering; and I concur with them in saying that it is needless and uncertain in its results. In many cases have I used it, but prefer other methods.

Zeim makes an exploratory puncture through the alveolar arch, which is more painful and unsatisfactory than that through the inferior meatus.

Hartmann and Kaufmann irrigate through the natural orifice and treat through that opening, but usually this is most unpleasant and objectionable, and can only be done in skillful hands.

For diagnosis, Lennox Browne relies upon the old methods—viz.: discharge of a fluid of the consistence of cream, of a pale lemon-yellow color, and, as a rule, unconnected with any ulceration or inflammation of the rhino-mucosa of the affected side and generally unilateral, and the patient is always aware of the offensive character of the flux. He says that in illumination pus may almost always be seen oozing from under the anterior extremity of the middle turbinated bone, and if this be wiped away, and the patient made to lie on a couch, with head slightly bent downward, the secretion will reappear. Also, there is generally pressure, redness, pain in that region, in eye, fullness of nose, etc.

\* Read before the Kings County Medical Association of Brooklyn.

This may do very well when these points are clearly developed, but is useless in cases in which there is no pus. When in doubt, he recommends puncture through the alveolus, canine fossæ, or the wall of the middle or inferior meatus.

These methods are all good, but in my opinion, based on past experience and that of others, I have come to the conclusion that the most feasible and practical way of diagnosis is by electrical illumination, now practised by but few. I believe it was first introduced by Voltolini, and later in Vienna privately by Chiari, and in the clinic of the late Dr. Schnitzler, where I have seen it used quite extensively. Not only has the electric light been found a convenient, painless, and reliable diagnostic measure in antral disease, and other sinuses about the head and face, but in the stomach, rectum, bladder, etc., and what developments await us in the future we know not.

As already stated, the present methods employed are usually painful, and that of syringing *via* the middle meatus is to most persons extremely unpleasant, and even in skillful hands great difficulties are often experienced in reaching the natural orifice.

To the use of the electric light in the mouth there can be none of these objections, and if in the future, after greater experience and better instruments, full reliance is found possible, a great gain will be secured; for the lamps may be put to many uses in diagnosis, not only in disease of the antrum of Highmore, but in frontal and ethmoidal disease as well. In the latter, however, I have found the light of little use, although in the hands of others partial success has been attained. Still, many say that it is of no practical value, but I think I may be able to prove that it is of real, not assumed, practical value.

I have been using one of Leiter's lamps, of about three candle power, which was most satisfactory; but this lamp having given out, and not being able to replace it with another, I have more recently been using one of Meyrowitz's, of about one candle power, and find this nearly as good as the higher; but of course the light spots are not so well defined as with the greater power. The handle is so arranged that the current may be turned on or off at will, and I do not press the button until the lamp is in the mouth and lips and nostrils are closed. The room must be absolutely dark, with not a ray of light to interfere with this delicate and accurate diagnostic method.

The points of diagnosis in illumination of the antrum are in appearances under the lower eyelid, over the antral sinus; if healthy, a large triangular light spot is seen, and, if clearly shown, we may be quite sure of a sound antrum. A more subdued illumination exists over the whole cheek and lips.

A good deal of practice is necessary to clearly and easily recognize the lines of demarcation. In well-developed antral disease the whole area of the antrum is in

the deepest shadow. Sometimes in health the antral area is dark, but very rarely is this the case.

The lamp may also be used for diagnosis in the nose, placed in the mouth and the nasal speculum used. The frontal sinus may be illuminated by placing the lamp under the orbital ridge, and in disease a dark shadow is formed. The normal tissues in these regions in persons of all ages are transparent, as is proved by the light, and in disease, no doubt, the umbra is caused by the hypertrophied condition of the mucous membrane and not the presence of fluid in the sinus. After all discharge has been cleared out the shadow still remains, and no means at our command can enlighten us as to the nature of the contents.

After diagnosis, the next consideration is the best method and point for opening and treating the maxillary sinus, and it is essential that an artificial opening, easy of access, be provided, where surgical measures may be carried on and perfect drainage effected, because in many cases very complicated conditions are found. To attempt the treatment of such cases through the natural canal is, to say the least, most unsatisfactory, as in many cases of disease it is imperforate, and if found, which is difficult, treatment through it yields little or no permanent results.

As already intimated, entrance to the antrum through the nasal wall as a means of diagnosis or treatment is most undesirable, as there are so many extensive diseased conditions of the sinus on which this method could throw no light, owing to the fact that there are many affections without purulent secretion, as polypoid degeneration of the antral mucosa, inspissated discharge, and in many cases locking up of fluids by septi.

Also, the approach to the sinus by the way of the alveolar process is almost as unsatisfactory as the other methods, because here it is almost impossible to make a proper exploration or diagnosis, or get good drainage or access for surgical purposes, and to sacrifice a sound tooth for such a purpose is open to criticism. If there is merely a little pus present, then this opening may answer every purpose, but how are we to tell that this alone is the condition?

I puncture through the anterior wall of the sinus at the canine fossæ. The lip is well retracted and a crucial incision made down to the bone. With an elevator the soft tissues are cleared away over quite a large space, say about the size of a silver twenty-five-cent piece. With a large burr in a dental engine the perforation is made through the bone and carefully enlarged with a small chisel to the size desired, being cautious that the contents of the antrum are not disturbed.

The sinus is now examined, with the electric light in the mouth or by reflection. If septa are present they are broken down, and polypi, if present, are removed, and if there is a granular or adenoid condition of the mucous membrane it is curetted. Sometimes hæmorrhage is excessive, but it is easily checked by packing the sinus

for a short time. The opening is made flush with the floor of the sinus, and a drainage-tube placed along its floor and allowed to remain a week or two. Occasionally a gold eyelet is put in, and the patient is thus in a position to syringe out the cavity at will.

The great difficulty is to keep the cavity open long enough, and subsequent repair is always perfect. The operation may be carried out under cocaine with but little pain, but I am in the habit of using bromide of ethyl for most cases. This general anæsthetic acts quickly, safely, and pleasantly. Professor Politzer, of Vienna, uses it almost exclusively in slight operations on the ear, and in the numerous cases in which I have seen him use it I have never observed the slightest unpleasant effect.

Some authors assert that carious teeth are the chief factors in antral troubles. Lennox Browne says that in forty-six cases recorded he found carious teeth present in all but three, but he does not state whether he believes the dental irritation is the cause of the trouble or not, but says that possibly the condition of the teeth may be caused by disease of the antrum. It is true that most persons afflicted with antral disease also have carious teeth, but I believe that only in rare cases are they produced by empyema of the antrum, and then only in those cases of necrosis of the floor of the sinus, or the rare cases of roots of teeth penetrating into that cavity.

Chiari, of Vienna, says that only in exceptional cases is the trouble caused by periostitis and abscesses at the root of the tooth, and occasionally the mere extraction of a tooth will effect a cure. Sometimes repair follows the frequent irrigation of the nose by medicated fluids and by the way of the natural orifice, but oftener only improves the trouble. Only recent inflammations may be so handled with any degree of success or certainty.

Probably in the greater number of cases of nasal blennorrhœa presented to the specialist, the seat of discharge is the maxillary sinus, and I do not believe the fetidity of the pus to be an important factor in diagnosis, as the odor seems more to depend upon the length of time the pus is pent up by sœpti, etc., than by the place of origination.

**CASE I.**—A gentleman, merchant, American, aged fifty-four years, presented himself at my office complaining of stoppage of the left nostril and a most fetid discharge from the same, which permeated every room where he sat, making life not only disagreeable to himself but to all others in the house as well. On examination I found the nostril filled with a muco-purulent secretion of the most offensive character. An antiseptic spray was used for several days and the discharge somewhat abated, and on a second inspection several large polypi were discovered, extending into the postnares; these I removed by snare, and cauterized the bases as well as possible with the electro-cautery. Very marked atrophy had taken place. The discharge was soon controlled, but fetidity remained as bad as ever, and as there were no visible indications of disease I sus-

pected antral trouble, and with electric light in the mouth found the following: the whole antral area on the left side was in deep shadow, whereas the light-spot showed distinctly over the antrum on the right side, thus convincing me that the left sinus was diseased; but as to its nature I was still in the dark. I endeavored to irrigate through the natural orifice by means of the Hartmann cannula, but with no success. The patient's teeth were in excellent condition and the mucous membrane was healthy. I concluded that this was a good case for operation, but he being in delicate health I thought better to delay for a time, and in the meantime kept up treatment of the nose.

A few days later, however, on one of his visits, he called my attention to a sore over the socket of the second superior left bicuspid, where that tooth had been extracted some weeks before, but the tissues at my first examination seemed perfectly healthy, and now considerably swollen and abraded, presenting an ugly appearance. It was most suspicious and I was somewhat puzzled as to its nature, but I treated it the best I could and he retired, only to return a few days later to tell me that it was rapidly increasing; and on looking I found that it had considerably extended along the alveolus.

With a probe I entered the mass, and, as there was only the slightest pain, concluded to see how far it would go, and, to my surprise, it first came in contact with necrosed bone which it penetrated, and continued on to the floor of the orbit. Hæmorrhage resulted through the natural orifice, but soon ceased. I now decided that I had cancer to deal with, so excised a portion; I examined it microscopically myself and had it examined by the pathologist at Harvard, my diagnosis being confirmed. The increase was very rapid, and soon prevented closure of the jaws and extended the whole length of the palate. Hæmorrhage on several occasions was profuse. The fetidity was extreme and remained about the same from the first time I saw him.

There was nothing in this case at first to indicate disease of antrum excepting the shadow test and odor; no pain, swelling, redness, discharge, or pressure. He died twenty-five days after I first saw the sore.

I should have stated that toward the last there was displacement upward of the floor of the orbit and walls of the nose, severe pain in the eye, etc.

**CASE II.**—A woman, twenty-four years of age, had a fetid discharge from the right nostril, and after irrigation and drying I found the middle meatus bathed with thick pus and partially blocked with some small polypi, which were removed. Antiseptic washes were used in the shape of sprays, and after a few days the discharge abated greatly, but as the patient reclined on the left side more pus would at once appear. Here it was evident that we had a case of empyema of the antrum to deal with. All teeth were in place and healthy.

By the use of Hartmann's cannula the sinus was quite easily reached and washed with medicated lotions several times daily with good effect temporarily, but a few months later the patient was worse than at first. By electric illumination the left side was very clearly lighted, while the right side was quite dark.

An operation was decided upon and anæsthesia produced by bromide of ethyl, and the antrum opened and pus removed through the artificial opening and the nasal fossa. I could find no cause for the trouble. There was some thickening of mucosa, which would account for the shadow.

I treated it by boric-acid solution at first and later

with zinc chloride, ten grains to the ounce, and the repair was perfect. In this case, as is shown, it seemed impossible to obtain good results through the nasal fossa.

CASE III.—Steven J., aged sixty-four years, mechanical engineer, was kicked on the nose by a horse without a shoe, ten years previous. There was considerable swelling and inflammation at the time and stoppage of the nostrils. From that time he has had constant trouble.

The septum was deflected to the left side and there was marked hypertrophy of the right middle turbinate. There were several polypi in each nostril and very little pus. He was a great sufferer from asthma. Both antra were in deep shadow under the electric light. I removed the polypi and hypertrophied tissue.

I gave chloroform and, as usual, opened through the canine fossa into both antra. On the left side the antrum was divided by a septum, locking up a quantity of pus of extreme fetidity. I irrigated and found the mucous membrane much infiltrated.

On my attempting to break through the septum the whole thing was found in a state of necrosis and immediately collapsed; behind, the cavity was plugged with a thick purulent caseous mass. I curetted very freely, irrigated, and put in a drainage-tube. The right side was found one of simple empyema and thickened mucosa, with an inspissated mass blocking up the nasal orifice. It was curetted and carefully treated. On this side the repair was quick and thorough, but the left remained some time in a diseased condition; but by persistence and keeping the opening patent, the repair eventually became perfect. The nares remained free of disease, asthma disappeared, and he became as it were a new man.

In the two cases mentioned the restitution was so perfect that the light reflex became clear. The discharge is free through the natural orifice, and the health is much improved.

In many cases I find ear complications, particularly tinnitus.

215 JEFFERSON AVENUE.

## SEASICKNESS: ITS CAUSE AND RELIEF.

By JAMES L. MINOR, M. D.,  
MEMPHIS, TENN.

In the *Memphis Journal of the Medical Sciences* for October, 1889, I advanced the theory of the aural origin of seasickness, basing my conclusions upon The Freedom of Deaf-mutes from Seasickness, and its Bearing upon the Theory of Seasickness and its Treatment, which was the title of my article. In a trip across the Atlantic I had observed the entire absence of all symptoms of seasickness in a party of five deaf-mutes. Indeed, their freedom from any annoyance of the kind, and the excellent appetites they enjoyed and gratified, while others around them were suffering from seasickness, excited general comment. Inquiry elicited the fact that deaf-mutes so rarely suffered from seasickness as to be, as a class, practically free from the disorder under all circumstances. Through the courtesy of Mr. Hasen-

tab, of the Illinois Institute for the Deaf, at Jacksonville, Illinois, who was one of the party, it was learned that out of a party of twenty-two deaf-mutes who crossed the Atlantic two months previously, not one suffered in the slightest degree from any form of seasickness, and yet a number of other passengers succumbed to it. Later, this party crossed that most trying of all bodies of water, the English Channel, and the same immunity was observed, though the passage was a rough one, and almost every other passenger on board became seasick. He also told me that he once made the trip from San Francisco to Portland by sea, with about thirty other deaf-mutes, that only one of these suffered from seasickness, and he had some disease of the ears which often caused dizziness and nausea at other times.

When it is remembered that only about three per cent. of persons crossing the ocean are entirely free from seasickness, it becomes evident that there must be some special cause for this freedom from it in deaf-mutes; and as the condition of the ears constitutes the only difference between the deaf-mute and the ordinary individual, it is naturally sought here.

It may be well to recall the fact that both physiological experiment and pathological observation point to that part of the inner ear known as the semicircular canals as exercising a controlling influence over the maintenance of the erect posture and the sense of equilibrium—functions frequently disturbed on shipboard.

It is generally conceded that seasickness is produced by the frequent and rapidly changing motions of the ship—conditions which it is the function of the semicircular canals to recognize and influence. Symptoms very similar to those of seasickness can be produced by turning around rapidly and frequently, or by swinging, and the cause is probably the same in each instance. And in diseased conditions of certain parts of the inner ear—the semicircular canals, in Ménière's disease—the symptoms are somewhat like those of seasickness.

Certainly if the foregoing deductions make probable the theory that the semicircular canals are sometimes concerned in the production of seasickness, then reasoning by induction establishes it beyond a doubt.

Deaf-mutes do not become seasick, nor do they suffer inconvenience—dizziness or nausea—when turned rapidly around, or when swinging. Moreover, it is a well-known fact that only in the irritative form of disease of the semicircular canals do dizziness, etc., appear, and that destructive disease of these parts does not produce either dizziness or nausea. Moos reports a case in which, after the falling out of a necrosed semicircular canal, deafness appeared, and with it permanent cessation of severe dizziness. And I have observed the same thing in one of my patients.

In deaf-mutes there is absolute deafness, or very great reduction in hearing, dependent upon destruction or serious impairment of function of the peripheral distribution or sound-perceptive elements of the audi-

tory nerve, in which process the semicircular canals are included.

These facts must force one to the conclusion that the reason why deaf-mutes do not suffer from seasickness is owing to the fact that their semicircular canals are destroyed or their sensibility impaired; and it is equally rational to suppose that others who suffer from seasickness do so because they have semicircular canals which are irritated by the frequent and varied motions of the ship.

Now, if by the use of any agent the semicircular canals can be anæsthetized, the value of these conclusions would be settled at once. I suggested the use of oleate of cocaine, putting a few drops in the ear every day or two, or oftener if necessary. Living in an interior town, however, I have had no opportunity of trying the drug in genuine cases of seasickness, and have had to limit myself to the induced and certainly allied affection—the dizziness and nausea produced by rapidly turning around. The results obtained have surpassed my expectations, and certainly suggest that the local use of cocaine in the ears may prove a most valuable remedy against that *bête noire* of ocean travel, seasickness.

I experimented with twenty-four healthy-eared individuals, and found that forty revolutions to the minute constituted rapid turning; that three or four such revolutions were sufficient to cause dizziness and often a sense of nausea; that three drops of an eight-per-cent. solution of cocaine oleate, dropped into each ear, diminished the susceptibility to dizziness, etc., to such an extent that more than double the number of revolutions could be made before any inconvenience was felt; that when, from continued turning, the dizziness, etc., came on after the use of the cocaine, it was less pronounced and more transient than without it.

The effects of the cocaine begin to manifest themselves in from twenty minutes to half an hour, and last from four to six hours.

I should say, then, that seasickness was a manifestation of irritation of the semicircular canals caused by the frequent and varied movements of the ship; that any drug which will lessen the irritability of the semicircular canals was a rational remedy for seasickness, and that a solution of cocaine dropped into the ears was such a remedy.

### Therapeutical Notes.

**Ichthyol in the Treatment of Intestinal Disorders.**—Guinzburg (*Médecine moderne*, May 13, 1896; *Therapeutique Gazette*, September, 1896) has strongly recommended the use of ichthyol in intestinal disorders, particularly those which accompany affections of the genito-urinary tract in women. The dose is four or five grains a day, preferably in keratin-coated pills, which are believed to pass through the stomach undissolved—

thus disagreeable taste and eructations are avoided. The medicine is best given some little time after meals. Good results were obtained in cases of diarrhœa: the appetite improved, the abdominal pains were much decreased, and the patient gained in weight; at the same time, if there was a tendency to menorrhagia, the menstrual function became more nearly normal. The best results were in cases of rebellious constipation. He failed to meet with any disagreeable symptoms such as are recorded by Bouchonief, who found that in persons suffering from renal disease or from chlorosis ichthyol was apt to produce loss of appetite, nausea, and vomiting. He attributes these disagreeable results to too large doses.

**Note on the Treatment of Measles.**—The following abstract from the *Lancet* for June 20th is published in the September number of the *Glasgow Medical Journal*: In the early part of the present year, an epidemic of measles of severe type attacked Northampton and the neighborhood. This afforded an opportunity to study the effects of treatment upon a large scale, and Mr. Dunley Owen, who had under his care upward of three hundred of the affected children, expresses the conviction that his low death-rate—only four children died—was due to the steady application of jacket poultices to the chest. He ordered the poultices as soon as there was reasonable ground to suspect an attack of measles, and before the rash appeared. This proceeding, he believes, lessens the risk of pulmonary complications assuming a serious form.

**A New Traumaticin.**—According to the *Revue internationale de médecine et de chirurgie* for September 25th, a form of traumaticin that is used in the dermatological clinic in Berne is made by Ducommun's method, that is, by mixing a watery solution of soap with a solution of alum. A magma consisting of a compound of aluminum and fatty acids is formed. The excess of water is squeezed out of this mass with the fingers, and the residue, while still moist, is dissolved in ether.

**The Mignonette as a Vermifuge.**—The *Journal de médecine de Paris* for October 4th states that in Russia the mignonette (*Reseda luteola*) has long been held in great popular esteem as a remedy against tapeworm, and tells of a woman who, fasting, took a very strong decoction of the flowers and then a large dose of castor oil, and three hours afterward voided the tapeworm in the form of a ball.

**An Application for Furuncles of the Eyelid.**—Lan-dolt and Gigax are credited in the *Wiener klinische Rundschau* with the following formula, intended for use in stubborn cases:

- |   |                       |                    |            |
|---|-----------------------|--------------------|------------|
| R | Tincture of camphor,  | { of each. . . . . | 15 grains; |
|   | Precipitated sulphur, |                    |            |
|   | Limewater,            | { of each. . . . . | 150 "      |
|   | Rose water,           |                    |            |
|   | Gum arabic. . . . .   | 3 "                |            |

M. To be painted on the lids once a day.

**Naphthalene in the Treatment of Dysentery.**—Kartulis (*Semaine médicale; Progrès médical*) recommends the following formula:

- |   |                              |                |
|---|------------------------------|----------------|
| R | Naphthalene. . . . .         | 15 grains;     |
|   | Calomel. . . . .             | 8 "            |
|   | Essence of bergamot. . . . . | 3 drops;       |
|   | Sugar. . . . .               | a sufficiency. |

M. Divide into ten wafers. One to be taken every hour.

THE  
NEW YORK MEDICAL JOURNAL,  
*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 17, 1896.

A COMPLAINT AGAINST THE PARIS PASTEUR  
INSTITUTE.

It is well known, says the *Journal de médecine de Paris*, that for several years now the Institut Pasteur has been a commercial establishment, a sort of factory for pharmaceutical products intended for subcutaneous employment. In the rue Dutot they sell viruses against diphtheria, against puerperal fever, etc.; furthermore, the establishment has obtained the monopoly of the manufacture of these various products. It is not generally known, however, that the institute has extended its operations and now makes also viruses for the destruction of injurious animals, such as insects. A learned foreigner attached to the concern, M. Danysz, has just discovered a virus sure to kill rats and mice, but the system, cried up with the usual flourish of trumpets, has not given the results expected of it.

A well-known veterinarian, M. Eloire, has published in an Amiens agricultural newspaper an article in which he states with regret that he has carried out the Danysz process conscientiously and has failed completely. Moreover, he declares that viruses prepared in the institute and intended to be used as preventives of diseases of animals have proved equally inefficacious. This is not the first time, he says, that there has been reason to complain of the products of the establishment founded by the lamented Pasteur. The chicken-cholera "vaccine" was only the starting point of gross errors, and they have returned to it. The rabbit cholera made a complete failure in Australia in the hands of M. Loir, a pupil and relation of the master, and last year the anthrax "vaccine" caused M. Eloire very serious disappointments, so that the mortality in the herd kept on after the inoculation quite the same as before it.

M. Eloire promises to recur to this highly interesting matter at some future time. In the mean time he remarks that the preventive inoculation of rabies leaves so much to be desired that it is not worth while to insist on it. As for the Danysz viruses, he says, they are a continuance of the unfortunate series of uncontrolled preparations sold for their weight in gold and not worth a nail. He protests that he is far from denying the discoveries of the illustrious master of French science; on the contrary, he says he is one of the constant patrons

of the "vaccine-mill," and it is precisely in this capacity that he finds the products of the institute too often lacking in the quality that one has the right to expect in articles obtained from such a source. Etiquette, he adds, is sometimes of no value.

Our Paris contemporary declares that this accusation comes from too good a source not to find an echo in the medical and veterinary world, and it reminds Dr. Roux and M. Duclaux, the successors of the illustrious founder, that they have a serious duty to fulfill, in which it hopes they will not fail.

PÆDIATRICS AS A SPECIALTY.

DR. SAMUEL W. KELLEY, the editor of the *Cleveland Medical Gazette*, has made a study of the extent to which pædiatrics is taught in the medical schools of the United States and Canada and in some of the schools in the United Kingdom. In a presidential address delivered before the Ohio State Pædiatric Society last May, published in the September number of the *Gazette*, he gives the points as to which he especially inquired and the information as to facts that he received from the various schools, together with expressions of opinion—very diverse, it may be remarked—concerning the degree to which it is practicable or desirable to make the diseases of children an exclusive specialty. What he says shows very plainly that during the last ten years great progress has been made in the teaching of pædiatrics, and that the branch has been so raised in rank in the curriculum that in several schools an examination in it must be passed satisfactorily or the candidate can not get his medical degree. We rarely hear now of a man's being "professor of obstetrics and diseases of women and children," which was quite the regular thing thirty years ago.

With regard to the strict specialization of pædiatrics, Dr. Kelley himself seems to expect it and to consider it desirable. He does not agree with those who expect it to do no more than keep pace with the march of general medicine and surgery. The progress it has made in the past twenty years, the number and value of recent additions to its literature, the promptness with which every new discovery in medicine is applied to it when practicable, and the zeal with which earnest workers are pursuing special investigations in it make him believe that pædiatrics is destined to make a rapid advance before long. He thinks that within the next decade it will stand out as distinct a specialty as gynecology, but he hopes it will not be "boomed" to the same extent as gynecology was when almost every doctor seemed "possessed with the idea that nothing less

than God's final and finest piece of handiwork was good enough for him to practise upon." He does not think pædiatrics will ever be so overdone.

### MINOR PARAGRAPHS.

#### RUPTURE OF THE URETHRA DURING COITUS.

Dr. H. GANZ (*Prager medicinische Wochenschrift*, 1896, No. 26; *Centralblatt für Chirurgie*, September 19, 1896) relates the case of a man who was attacked during coitus with a severe pain in the region of the neck of the glans penis and a considerable hæmorrhage from the urethra. He found the penis quite tender, but neither swollen nor ecchymotic; so it is doubtful if the injury extended beyond the mucous membrane.

### ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 13, 1896:

DISEASES.	Week ending Oct. 6.		Week ending Oct. 13.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	35	7	29	5
Scarlet fever.....	48	7	51	1
Cerebro-spinal meningitis....	0	0	1	1
Measles.....	20	6	39	5
Diphtheria.....	169	16	173	25
Tuberculosis.....	158	107	109	75

**The Late Dr. William Remsen Taylor, of Astoria.**—At a special meeting of the medical board of the Astoria Hospital, held on October 6, 1896, action was taken as follows:

The medical board desire to pay tribute to the memory of William Remsen Taylor, M. D., late president of this institution.

*Whereas*, The medical board, in the death of Dr. Taylor, have lost their first executive officer and long-tried friend; therefore be it

*Resolved*, That the medical board cause to be spread upon the minutes of its records their resolutions of appreciation and sorrow.

*Resolved, further*, That the sympathy of this board be extended to the members of his family; also that a copy of these resolutions be forwarded to them and be published.

[Signed,] NEIL O. FITCH,  
JAMES D. TRASK,  
CLARENCE N. PLATT, ) Committee.

**The Late Dr. Edward S. Farrington.**—The West End Medical Society has issued the following:

It is with deep regret that we learn, at this our first meeting of the year, of the death of our esteemed fellow-member, Dr. Edward S. Farrington, who died on September 7th, of typhoid fever.

He was a man of fine character, scholarly attainments, and attractive personality, and was held in high esteem by all who knew him.

We feel that by his death both the society and the individual members thereof have lost a valuable associate and a good and loyal friend.

We hereby resolve that these, our expressions of regret and appreciation of our loss be spread upon the minutes of this society, and that copies thereof be transmitted to his family and to the current medical journals.

[Signed,] CYRUS J. STONG,  
HOWARD GILLESPIE MYERS,  
CHARLES GOOD,  
EDWARD L. WILLIAMSON, ) Committee.

**The Buffalo Academy of Medicine.**—At the last regular meeting of the Section in Medicine, on Tuesday evening, the 13th inst., the following papers were to be read: 'The Use of the Stomach Tube, by Dr. A. L. Benedict; Acute Pleural Effusions in Children, by Dr. J. C. Clemensha; and The Dangers of Over-bicycling, with a Report of a Case, by Dr. W. C. Krauss.

**The Society of Medical Jurisprudence.**—At the last regular meeting, on Monday evening, the 12th inst., a paper entitled *The Enemies of Sanitary Science* was to be read by Dr. Daniel Lewis.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 27 to October 10, 1896:*

DAVIS, WILLIAM B., Captain and Assistant Surgeon, will be relieved, by direction of the Secretary of War, from duty as attending surgeon and examiner of recruits in Newport City upon the expiration of the leave of absence granted him in S. O. No. 230, A. G. O., September 30, 1896, instead of the conclusion of his examination for promotion as heretofore ordered by Paragraph 2, S. O. No. 214, A. G. O., September 11, 1896.

DE SHON, GEORGE D., First Lieutenant and Assistant Surgeon, is granted leave of absence for four months, to take effect after he shall have reported for duty at Washington Barracks, D. C.

By direction of the Secretary of War, ALDEN, CHARLES H., Colonel and Assistant Surgeon General, and DE WITT, CALVIN, Major and Surgeon, are detailed as delegates to represent the medical department of the army at the Second Pan-American Medical Congress to be held in the City of Mexico from November 16th to November 19th.

#### Promotion.

DAVIS, WILLIAM B., Captain and Assistant Surgeon, to be Surgeon with the rank of Major, August 11, 1896, vice WORTHINGTON, deceased.

#### Society Meetings for the Coming Week:

MONDAY, October 19th: New York Academy of Medicine (Section in Ophthalmology and Otology); New York County Medical Association; Boston Society for Medical Improvement; Cleveland Society of the Medical Sciences; Hartford, Connecticut, Medical Society; Chicago Medical Society.

TUESDAY, October 20th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Kings, St. Lawrence (semi-annual), and Westchester (White Plains), N. Y.; Hunterdon, New Jersey, County Medical Society (Flemington); Baltimore Academy of Medicine.

WEDNESDAY, October 21st: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society.

THURSDAY, October 22d: New York Academy of Medicine (Section in Obstetrics and Gynecology); New York Orthopedic Society; Brooklyn Pathological Society; Roxbury, Massachusetts, Society for Medical Improvement (private); Pathological Society of Philadelphia.

FRIDAY, October 23d: New York Clinical Society (private); New York Society of German Physicians; Yorkville Medical Association (private), New York; Philadelphia Clinical Society; Philadelphia Laryngological Society; St. Louis Academy of Medical and Surgical Sciences; Cleveland Medical Society.

SATURDAY, October 24th: New York Medical and Surgical Society (private); St. Louis Medical Society.

#### Answers to Correspondents:

No. 452.—1. We know of no book on the subject. 2. Of the Health Department of the City of New York.

No. 453.—1. Emmet's *Principles and Practice of Gynecology*. 2. Bernutz and Goupil.

## Births, Marriages, and Deaths.

### Married.

BULLOCK—RODENBROUGH.—In New York, on Thursday, October 8th, Dr. Earl Sprague Bullock and Miss Nina Rodenbrough.

EVANS—THOMPSON.—In Milwaukee, on Thursday, October 8th, Dr. Robert Evans, of Fort Dodge, Iowa, and Miss Mercie Thompson.

GRANT—BOISSEAU.—In Allendale, Louisiana, on Thursday, October 8th, Dr. Robert L. Grant, of Texarkana, Texas, and Miss Bettie Boisseau.

SIMMONS—ANDREWS.—In Alexandria, Louisiana, on Wednesday, October 7th, Dr. R. O. Simmons and Miss Laura Andrews.

STEWART—MORRIS.—In New York, on Wednesday, October 14th, Dr. William Holmes Stewart and Miss Florence M. Morris.

### Died.

BRAGDON.—In Martinez, California, on Thursday, September 3d, Dr. Edmund Bragdon, aged fifty-three years.

BUCKALEW.—In Pollock, Louisiana, on Sunday, October 4th, Dr. W. B. Buckalew, aged fifty-five years.

GEHLBACH.—In New Orleans, on Monday, October 5th, Dr. Charles Gehlbach, aged forty-six years.

O'SULLIVAN.—In Brooklyn, on Sunday, October 11th, Dr. George B. O'Sullivan, aged thirty years.

PARDEE.—In Oakland, California, on Tuesday, September 22d, Dr. E. H. Pardee.

TRENOR.—In Alameda, California, on Thursday, September 17th, Dr. Eustace Trenor, aged sixty-two years.

## Letters to the Editor.

### A METHOD OF TREATING CANCER.

No. 1037 CAROLINE STREET, BALTIMORE, October 13, 1896.

To the Editor of the New York Medical Journal:

SIR: The article in the October 10th issue of the *Journal*, Chelidonium in the Treatment of Cancer, interests me much. You say you hope this simple treatment will have further trials in combating so dreadful a disease as cancer. Will you let me come into the fold with a treatment quite as simple and speedy as it? I allege nothing new for my treatment, but know it has been successful, in my hands, in such cases as I have come across in my general practice.

Stated briefly, I proceed as follows: Given a case of epithelioma or other form of cancer, I first carefully cleanse the surface of the diseased part with pyrozone, then dry it carefully. Using a ten-per-cent. solution of cocaine, I make the part fully anæsthetic. To the surface I then apply a full-strength solution of sodium ethylate. This strength is got by allowing the crystals (Merck's) to deliquesce. Then I apply a powder made as follows:

B. Acetanilide . . . . .	1 drachm ;
Aristol . . . . .	2 drachms ;
Boric acid . . . . .	1 ounce.

This powder is put on thick over the whole diseased surface. I then spread lightly with vaseline a piece of sheet wadding large enough to cover the whole surface, and put absorbent cotton and a bandage over this. This treatment is repeated as often as necessary, and a cure follows in from two to five weeks, according to the

amount of tissue involved and the patient's general condition.

During the time of treatment, the patient gets internally a three-grain tablet of protonuclein (R. & C.) three times a day. This is a most necessary part of the treatment. The value of protonuclein to increase the white corpuscles I need not dwell on here. Sufficient it is to say I believe the other treatment would be valueless without help from this agent.

I place my patient in such a position as to bring the bottom of the area horizontal, and fill the cavity with pyrozone, first having wiped all secretion carefully away, because this saves time. Then when the "boiling" ceases I dry the parts with absorbent cotton and pour in the cocaine, wait five minutes for it to act, and then dry it out with the cotton.

There is no more painful caustic than the ethylate, and even the precaution of using cocaine does not always entirely control the pain. When the ethylate touches the surface a peculiar change is noticed. If the wound is clean the fluid spreads itself out rapidly, and where there is diseased tissue the part instantly turns black. The rest of the surface becomes brown. If the wound is not clean and is filled with the discharge of the cancer, the whole surface turns black.

One application is made at first over the whole surface. As soon as the black color is seen, the preparation becomes very gummy and tenacious, and should not be disturbed. Then the powder is dusted on, packing the wound fully. Considerable edema follows the first application, but soon disappears, and any pain stops as soon as the caustic action ceases by all of the agent being used up. The protonuclein no doubt helps here materially to remove the edema.

The vaseline is used on the wadding to prevent the dressings from sticking to the wound, and the cotton over it catches any discharge. It is remarkable what a soothing effect the vaseline has to the wound, and perhaps it aids in limiting the pain.

It is my practice to see the patient and dress the sore every second day, beginning just as if the case were a new one. But I am careful, as the cure progresses, to touch only such points as show disease and to avoid any forcible removal of dressings, so as not to disturb the parts and to prevent bleeding. It is necessary to use a glass rod in applying the ethylate, because of its excessive corrosive action, and it is almost impossible to keep it in a glass-stoppered bottle. I keep it in small corked bottles and am careful not to let it touch the cork.

I have had four cases of epithelioma this year and have cured them all by this method. If this is worthy of room in your columns I shall be glad. For if it is the means of curing one case I shall consider my time very well spent. I will answer any questions gladly so far as I am able, and will show one cure, in a patient who has consented to this, to any physician who is near enough and who is interested.

For six years I have looked for a cure for epithelioma, and feel very sure that this treatment will answer in nearly all cases. I do not allege it to be a specific by any means. I do not remember where I first heard of the ethylate. It is interesting to note, however, that in the *Medical Summary* for October brief mention is made of such use for this agent. I use acetanilide and boric acid because of their well-known germicidal properties, and aristol because we have no better healing and scar-forming agent. ALBERT S. ATKINSON, M. D.

## THE UNAUTHORIZED USE OF A NAME.

BACTERIOLOGICAL DIVISION OF THE BUREAU OF HEALTH,  
PHILADELPHIA, October 6, 1896.*To the Editor of the New York Medical Journal:*

SIR: My name has been recently coupled with a recommendation of a certain patented disinfectant. This has been done in the newspapers, and also in some of the medical magazines. I wish hereby to protest emphatically against any such use of my name. It has been done without my knowledge or consent.

B. MEADE BOLTON, M. D.

## FATAL CASES OF HICCOUGH.

No. 1138 MADISON AVENUE, NEW YORK, October 13, 1896.

*To the Editor of the New York Medical Journal:*

SIR: I should be greatly obliged to you if you would be kind enough to allow me to say through the columns of your valuable journal that I should be greatly pleased to have the addresses of the medical gentlemen who have had the opportunity of attending cases of protracted (and in most instances, I believe, fatal) hiccup, that have been mentioned lately in the telegraphic news of our daily papers.

H. ILLOWAY, M. D.

## Reports on the Progress of Medicine.

## OTOLOGY.

By CHARLES STEDMAN BULL, M. D.

**Acute Infantile Inflammation of the Labyrinth.**—

Compaired (*Rev. hebdom. de laryngol. et d'otologie*, May 16, 1896) considers it of extreme rarity, as the aurist usually sees the case after the damage has been done. The disease advances with alarming rapidity and is accompanied by grave symptoms of an obscure nature, which, however, are not appreciated in many cases, and are often confounded with those of acute meningitis. The case naturally comes under the care of the family physician, and is treated as acute meningitis, typhoid fever, acute hydrocephalus, etc. In the first case cited, the labyrinthine inflammation followed a parotiditis. The second case seemed to be primary and its cause was unknown. The disease is often confounded with typhoid fever and infantile meningitis. In typhoid fever the deafness appears at an advanced period of the disease, while in labyrinthine disease it is an early symptom. In typhoid fever vertigo is not present, while in labyrinthine disease it is never absent. In typhoid fever there is not in the beginning any headache, or pain in the ear, or delirium, all of which are present early in labyrinthine disease. Meningitis is almost always fatal, while most cases of labyrinthine disease recover. The paralytic met with in meningitis do not occur in labyrinthine disease.

**The Pathological Changes in the Labyrinth.**—Politzer (*Rev. de laryngol. et d'otologie*, November, 1895) divides these changes into three classes: 1. Hyperemia. 2. Hemorrhagic extravasations. 3. Inflammation, whether primary or secondary, and its consequences.

The anatomical changes produced in the course of infectious maladies come from the invasion of specific

microbes or of purulent matters into the labyrinth. These changes are more or less intense, according to the degree of inflammation, and consist of swelling and thickening of the labyrinthine lining, numerous filaments extending between the bony walls and membranous parts. These may exist in the aqueduct of the vestibule, in the ramifications of the auditory nerve, or in the bony cavities of the petrous bone. These changes are very much the same in all infectious diseases. The disorganizing effect of the streptococcus is shown by a fatty degeneration of the endothelium of the blood-vessels, leading to coagulation and thrombosis in these vessels.

The changes which result from cerebro-spinal meningitis come from a suppurative inflammation of the labyrinth, and consist in a destruction and atrophy of the membranous labyrinth and ramifications of the auditory nerve, partial or total destruction of the organ of Corti, atrophy of the cells of the spiral ganglion, and a deposit of detritus, with neoplastic formation of connective tissue and partial ossification of the latter.

Secondary lesions of the labyrinth frequently occur in the course of chronic suppuration of the middle ear, sometimes without appreciable lesion of the labyrinthine wall, by extension of the pathological changes through the blood-vessels and lymphatics. Any obstacle in the internal auditory canal which compresses the blood-vessels within this canal may lead to exudations into the labyrinth.

The labyrinth may also be affected in cases of leucæmia as follows: 1. By the new formation of connective and bony tissue in the tympanic wedge of the cochlea. 2. By complete invasion of the semicircular canals by connective tissue. 3. By the accumulation of lymph cells within these canals, in the vestibule and cochlea.

Syphilis produces similar changes in the labyrinth. We find hyperostosis of the temporal bone, narrowing of the labyrinthine cavity and internal auditory canal, proliferation of the labyrinthine capsule, narrowing of the oval window, and ankylosis of the stapes. One of the rarer results of syphilis is atrophy of the cells of the spiral ganglion and of those of the nerve fibres of the acoustic nerve in the cochlea, and infiltration of the vascular walls with small cells.

Tuberculosis produces similar changes in the labyrinth, although no case of primary tuberculosis of this region has ever been reported.

**Permanent Artificial Perforation of the Drumhead.**

Miot (*Rev. hebdom. de laryngol. et d'otol.*, June 28, 1896) draws the following conclusions from his observations of certain cases of dry otitis media: The best means of completing the diagnosis is to make an incision in the posterior half of the drumhead, along the bony case, which improves the hearing, and should be large enough to see the incudo-stapedal articulation. To obtain a permanent opening is to remove the drumhead and the long process of the malleus, and place a plug of cotton for a few days *in situ*. The hearing after this operation is very variable, being sometimes better and sometimes much worse.

**Irrigation of the Drum Cavity by Means of a New Sound.**

—Courtaud (*Ann. des mal. de l'oreille et du larynx*, May, 1896) has devised a new hollow sound, absolutely rectilinear, with a lateral orifice at its extremity, which can work in a groove fixed in a handle, which makes an angle of a hundred and twenty degrees with the axis of the sound. Attached to a syringe by means

of a short rubber tube, the handle is seized between the left thumb and index finger, and the sound is introduced directly into the drum cavity through the perforation in the drumhead. The sound will do no damage if the patient moves, as it is rectilinear. The force of the injection may be graduated by more or less energetic pressure on the piston of the syringe.

**Tinnitus Aurium and Some Results obtained by its Treatment with Coniine Hydrobromide.**—Gomez (*Ann. of Ophth. and Otol.*, January, 1896) here reports the results of treatment by coniine hydrobromide of twenty-three cases of tinnitus aurium. Six cases were very much improved, six were slightly improved, one was entirely cured, and ten were not benefited at all. The best results were obtained in the cases in which both middle and internal ears were affected. The largest dose given was a thirtieth of a grain, and anything higher than this usually gave rise to gastric disturbances.

**The Electrical Treatment of Tinnitus Aurium.**—Jones (*Arch. of Otol.*, xxiv, 2 and 3) states that many patients can be relieved of the distressing symptom of tinnitus by a course of galvanism. He thinks that the auditory nerve can be acted upon in the best way by a bifurcated or divided electrode which can be applied to both ears at once. The parts in contact with the skin should be not less than two centimetres in diameter. A pad of moist absorbent wool should be placed between the electrode and the skin. The indifferent electrode is placed at the back of the neck, and a galvanometer and a rheostat should be included in the circuit, which enables the operator to introduce or remove a resistance of ten thousand ohms quite gradually. When everything is ready, the current is slowly and steadily raised by the current collector to five milliamperes. As the resistance of the skin diminishes, the current will increase slowly, the galvanometer being allowed to indicate eight to ten milliamperes. If the current should rise higher, the rheostat must be brought into use to keep it at the proper strength. The effect of the application of the anode to the ears should be to diminish the noises; that of the cathode to increase them. The reverse sometimes happens, however, and therefore the patient must be tested to find out whether the current modifies the sound. If diminution of the sounds be produced, the prospects of improvement are good. If neither the anode nor cathode alters the sounds the prognosis is unfavorable.

**Trephining the Mastoid.**—Castex (*Rev. hebdom. de laryngol. et d'otol.*, June 20, 1896) draws the following conclusions from his observations:

1. The great utility of opening the mastoid in young patients, who have not been cured of chronic suppurative discharges by medical treatment.
2. The importance of Henle's spine in discovering the mastoid antrum.
3. The possible anomalies in the situation of the lateral sinus, which may lie close to the anterior border of the apophysis.
4. The advantages of moist dressings and of disinfection of the nasopharynx in purulent inflammation of the middle ear.

**Mastoiditis with Sero-mucous Effusion; Evacuation by Compression of the Air in the Auditory Canal.**—Courtade (*Ann. des mal. de l'oreille et du larynx*, February, 1896) is of the opinion that in certain forms of acute suppurative otitis media the mastoid apophysis participates in the inflammatory process and becomes

filled with a sero-mucous liquid. The symptoms of this variety of mastoiditis are much less pronounced than those of the suppurative variety. The evacuation of the liquid is usually effected by the simple compression of the air in the auditory canal by means of Siegle's speculum.

**A New Mastoid Retractor.**—Thorner (*Ann. of Ophth. and Otol.*, iv, 4) has devised an instrument which consists of a flat S-shaped piece of steel or German silver, about an inch and three quarters long and three quarters of an inch broad. One of the extremities is shaped into a three- or four-pronged hook, while the other extremity forms a blunt, broad retractor bent in the opposite direction. When the bone is well denuded and the periosteum pushed aside, the prongs of one retractor are well hooked below the periosteum of the posterior margin of the wound, and the prongs of the other retractor below the parts of the anterior margin. Then a long strip of sterilized gauze about an inch and a half broad is folded in its middle over the blunt end of the anterior hook, drawn across the forehead and around the head of the patient, and fastened tightly over the blunt hook of the posterior retractor. In this manner the parts are not only held firmly separated, but the traction exercised upon the hooks by the strip of gauze or a rubber ring acts to a certain degree in a hæmostatic manner.

**Modification of the Operative Technique in Perforation of the Mastoid Apophysis.**—Courtade (*Ann. des mal. de l'oreille et du larynx*, February, 1896) has devised a retractor which fixes methodically the point for trephining. It consists of an ordinary surgeon's spatula bent at an elbow, one end of which has been narrowed so as to leave a beak four millimetres long on the prolongation of the median ridge on one of the surfaces of this instrument. As the spatula has a width of nine millimetres, a shoulder is formed on each side of the beak three millimetres wide. After the incision of the soft parts, two or three millimetres behind the retro-auricular groove, the periosteum is dissected up from the apophysis and from the posterior face of the auditory canal for a moderate extent. The spatula retractor is then so placed that its beak is directed about at the middle of the posterior wall of the bony canal and abuts against it when the assistant draws it forward. The retractor can not penetrate the auditory canal because of the presence of the shoulder on each side of the beak. The surgeon should then trephine the bone a few millimetres behind the spatula and within the space marked by the width of the latter, which will bring the opening directly in the dangerous zone.

In the child, the surgeon must be guided by the crest of the instrument which is found in the median line, which corresponds to the middle of the posterior wall of the bony meatus.

Another advantage of this spatula retractor is that it acts as a hæmostatic by compression of the anterior lip of the cutaneous wound.

**Certain Anomalies in the Mastoid Region.**—Moure (*Rev. hebdom. de laryngol. et d'otol.*, June 13, 1896) reports the results of his last thirty-four operations on the mastoid. In eighteen acute cases he found the antrum normal in size and position in fourteen. In three cases it was notably enlarged. In one case the antrum was very small, situated in front of the drum behind the posterior wall of the canal, and the lateral sinus occupied its place. The remaining sixteen cases were all cases of chronic suppuration. In seven he found an

eburnated apophysis with very small antrum, and in six of these it could not be found when the apophysis was opened in the usual way. In three other cases the antrum was very small, and the rest of the apophysis was replaced by the lateral sinus which was applied to the posterior wall of the auditory canal. In five cases the antrum was enlarged, but in only one of these was there any cellular structure in the apophysis.

**Right Suppurative Otitis Media; Extensive Thrombosis beginning in the Right Petro-squamous Sinus; Left Cerebellar Abscess.**—Cleveland (*Arch. of Otol.*, xxiv, 2) reports an interesting case of this sort in a boy aged six years. The boy had had earache with continuous discharge for about six months. There were two perforations in the drumhead. One month later the boy became drowsy, vomited, and had a rise of temperature. Ten days later the drumhead was incised and the pain relieved. At no time was there any symptom of trouble in the mastoid, but as the drowsiness continued, an exploratory opening was made in the bone with negative result, although the incision was carried into the digastric fossa for a considerable distance. The boy died comatose on the next morning. At the autopsy the longitudinal sinus was almost empty. At the anterior extremity of the petro-squamous sinus, on the right side, necrosis had taken place and pus had entered the sinus, causing a thrombus which extended backward into the lateral sinus. The right lateral sinus contained a purulent-looking thrombus which extended down into the jugular vein and around posteriorly into the left lateral sinus. Posteriorly in the left cerebellar fossa there was a considerable amount of grayish-yellow lymph. Both occipital lobes showed at their extremities small patches of a dark greenish-red color. Similar spots were found on the superior surface of the left cerebellar hemisphere posteriorly.

**The Treatment of Otitis Externa Circumscripta with Salicylic-Acid Collodion.**—Dunn (*Arch. of Otol.*, xxiv, 2) recommends for the local treatment of furuncular inflammation of the external ear a mixture of salicylic acid, one drachm, and collodion, one ounce, applied once daily. The combination relieves also the annoying itching which is so common in dry, scaly conditions of the external canal. Its application is painful for a brief period while the film is forming, but it prevents the spread of the inflammation beyond the point affected, and limits the inflamed area by constricting the adjacent skin.

**Purulent Otitis Media; Abscess in the Cerebellum; Death; Autopsy.**—Woodward (*Arch. of Otol.*, xxv, 1) reports a case of this nature in a boy aged thirteen years. The autopsy showed a purulent pachymeningitis on the posterior surface of the petrous portion of the left temporal bone, near the internal auditory foramen. The bone was carious. No blood clot was found in the lateral sinus. Several small apertures through the wall of the sinus communicated with the purulent focus beneath the dura. Adjacent to the latter the cortex of the left lateral lobe of the cerebellum was discolored, softened, and necrosed. Incision into this lobe showed that its entire interior had been converted into an abscess cavity full of foul-smelling pus. The white matter had been entirely destroyed. One small fibrous nodule was found in the pia mater about an inch to the left of the longitudinal sinus, opposite the extremity of the fissure of Rolando.

**Remarkable Improvement of the Hearing following Ossiculectomy in a Case of Otitis Media et Interna.**—

Alderton (*Ann. of Ophth. and Otol.*, April, 1896) reports the case of a man, aged twenty-nine years, who had been deaf in the left ear for nine years and in the right ear for five years, with constant hissing tinnitus. The tympanic membranes were slightly dulled. The watch was not heard on either side. Loud speech heard at one foot on both sides. Galton whistle heard at the mark 2.5 on the right and at 2.8 on the left. Weber heard on left side. The tympanic membrane, malleus, and incus of the left ear were removed, with immediate marked improvement in the hearing; whisper heard at five feet and speech at sixteen feet. This improvement was almost obliterated by the post-operative swelling and the subsequent discharge. As the swelling and discharge abated the improvement again manifested itself, and has increased, though the drum membrane has entirely reformed. The tinnitus was markedly lessened.

**A Contribution to the Diagnosis and Treatment of Cholesteatoma in Otitis Media Purulenta Chronica.**—Scheibe (*Arch. of Otol.*, xxv, 2) thinks that combining resection of the posterior wall of the meatus with opening the antrum not only assists in removing disease products, but gives a permanent wide opening to the diseased spaces either through the meatus or back of the auricle. He draws the following conclusions: 1. If urgent symptoms exist, chiseling of the mastoid with resection of the posterior wall of the meatus is at once undertaken. At the same time Siebenmann's procedure is employed. 2. If urgent symptoms are wanting, injections and insufflations by aid of the tympanic tube may be employed after removal of granulations by snare or curette. If the passage to the aditus be too narrow the malleus is removed. 3. Obstinate persistence of fetor, in spite of continued treatment, is an indication for resection of the posterior wall, even though severe complications are wanting.

**Acute Purulent Otitis Media with Bulging of the Posterior-superior Sector of the Tympanic Membrane.**—Escat (*Rev. de laryngol. et d'otol.*, August, 1895) draws the following conclusions from four cases of the above disease:

1. There is a circumscribed form of acute purulent otitis media, isolated otitis of the attic and of the greater part of the lower story of the tympanum.
2. This otitis seems to be encysted in the posterior pocket of von Tröltsch, or at least between the mucous folds behind this pocket.
3. It is characterized clinically by a limited bulging of the posterior-superior sector of the tympanum.
4. Catheterism, made after paracentesis, shows that the cavity has no communication with the rest of the tympanic cavity.
5. The prognosis is favorable.
6. The treatment should be: 1. Paracentesis of the posterior-superior sector. 2. Aspiration with Siegle's speculum. 3. Antiseptic dressings and occlusion of the meatus with sterilized cotton wool.

**A Contribution to the Study of Acute Inflammation of the Middle Ear produced by the Bacillus Pyocyaneus.**—Pes and Gradenigo (*Arch. of Otol.*, xxv, 2) here draw attention to the real significance of the *Bacillus pyocyaneus*. Recent researches have shown that it may be classed with those pyogenic germs which are capable of producing an infection of the entire organism. Its presence must, however, be regarded as an exceptional occurrence, and can be easily recognized by the characteristic color imparted to the pus. It has frequently been found in the discharge coming from the ear. It is

virulent only when in combination with pathogenic cocci. It imparts a green color to beef tea at 37° in twenty-four hours, which increases in intensity in the following days. After about three months the color changes to an olive-green. In the tube cultures the gelatin rapidly liquefies, taking on at the same time a bright greenish-blue color. At the junction with the unchanged gelatin a yellowish-white crumbling substance is deposited. The color gradually passes to a bright orange. The gelatin of the plate cultures also liquefies rapidly, and takes on a beautiful fluorescence. On agar the bacilli grow in round colonies, which become surrounded by white or smoky rings, while the entire surface of the agar appears green and opalescent. The bacillus is always capable, though changed in appearance by artificial culture, of setting up a localized diseased condition.

**A Rare Case of External Otitis of Infectious Origin.**—Szeues (*Ann. des mal. de l'oreille et du larynx*, October, 1895) reports a case occurring in a nurse aged twenty-six years. For four days she had complained of severe pain in one ear, which was very sensitive to the touch. The canal was full of fetid pus, and its orifice reduced to a minimum. The walls of the canal were dense and swollen, but when a small speculum was introduced and the canal was thoroughly cleansed, the drumhead was found to be intact and the hearing was much improved. The submaxillary glands were much enlarged. The patient stated that the baby whom she was nursing had been vaccinated the preceding week, and she thought that she had introduced some of the discharge from the pustules into her own ear, as she frequently scratched her ear with her fingers. She also showed a vaccine pustule on her own cheek near the angle of the mouth. By the continuous application of cold lotions and daily injection of a weak solution of lysol, the swelling and discharge slowly subsided, and the latter was subsequently changed to menthol on bits of cotton. The disease lasted for three weeks, but was eventually entirely cured.

**The Microbic Character of Acute Catarrhal Otitis Media.**—Lannois (*Ann. des mal. de l'oreille et du larynx*, June, 1896) concludes from his observations that: 1. The normal middle ear in animals acts like an aseptic cavity and contains no micro-organisms. 2. The liquid of catarrhal otitis media does or does not contain microbes, according to the period at which it is examined after the beginning. 3. The disappearance of the microbes is sometimes probably due to the bactericidal power of the mucous membrane and the mucus. 4. The bactericidal action explains why the secretion rarely becomes purulent, even after paracentesis and repeated catheterization.

**The Indications for Mastoid Operations in Acute Purulent Otitis Media.**—Knapp (*Arch. of Otol.*, xxiv, 3 and 4) draws the following conclusions from his observations:

1. There is in acute otitis media no symptom which by itself constitutes a sufficient indication for mastoid operation. Neither is there any one symptom which contraindicates it, with the exception, perhaps, of deep coma. The most important symptoms are local pain, spontaneous and on pressure, headache, rise or fall of temperature, dizziness, nausea, vomiting, stupor, aphasia, hemianopsia, optic neuritis, paralysis, and coma. Choked disc from otitic brain disease may disappear with either operative or spontaneous recovery of the patient.

2. The indication for operating is derived from the ensemble of the symptoms and the course of the disease.

3. Even if the patient does well, and seems cured, he should not be lost sight of for weeks or months, for acute purulent mastoiditis is a treacherous disease.

4. Whatever the symptoms be, we should, as a rule, begin the operation by opening the antrum, and then be guided by the conditions coming into view.

**History and Autopsy of Two Cases of Fatal Otitic Brain Disease.**—Knapp (*Arch. of Otol.*, xxiv, 2) reports two interesting cases. The first case was a typical abscess in the temporo-sphenoidal lobe, caused by chronic suppuration in the middle ear, and ended fatally by cerebral pressure from a large abscess without any further complications. The autopsy showed with convincing force the importance of a careful treatment of all chronic cases of otorrhœa, especially when offensive secretion, caries, and polypi are present. Here the indications are to be met only by a radical operation, consisting in the thorough evacuation of the tympanum and its accessory cavities, including the labyrinth.

The second case was an acute otitic retropharyngeal abscess, with purulent leptomeningitis of the convexity of the anterior lobes. It began with an acute purulent otitis media of the left ear and pursued anything but a typical course. At the autopsy, after taking out the brain and removing the temporal bone, the following remarkable condition presented itself: The upper part of the tympanic cavity was full of pus, which collected along the dilated semicircular pro tensor tympani, in the tissues surrounding the tube, and formed a prominence in the upper pharyngeal cavity. A probe passed from the attic through the pus pushed forward the left half of the soft palate, and could there be felt with the index finger introduced through the mouth.

(To be concluded.)

## Miscellany.

**Intramuscular Injections of Saline Solutions in Intense Albuminuria and Uræmia.**—In the *Province médicale* for September 19th M. F. Dumarest gives a detailed account of his experience with this treatment and of the results obtained therefrom. He cites a number of cases to prove the efficacy of the treatment, and states that in two of them he was struck with the rapid improvement in the general condition and the consecutive disappearance of the edema and the albuminuria. After the injections, two orders of symptoms were observed: The first, and in some degree provisional, was the improvement in the pulse, in the energy of the heart, in the mental condition, and in the disappearance of the so-called toxic symptoms, which revealed an antitoxic influence probably connected with the dilution of the poisons. The later symptoms, polyuria, diarrhœa, and sweating, were more efficacious and more lasting, and exercised an eliminating action. Phlebotomy, says the author, may act as a substitute for antitoxic medication, but it is only a palliative, while injections of salt water possess a curative value owing to their eliminating action. M. Dumarest sums up his experience in the following conclusions: 1. These injections are not contraindicated by renal alterations. On the contrary, they exert the best influence on the toxic

symptoms due to these alterations, and even on simple albuminuria. 2. Pulmonary oedema and anasarca do not constitute an obstacle to this method; combined with phlebotomy, it is an heroic measure which should be resorted to all the more if the complications are more numerous and the situation is more serious. 3. Salt water probably acts by a double mechanism: Tonic and antitoxic in the beginning, which is palliative, and secondarily, eliminating, which is curative. 4. These injections are pre-eminently the proper means of treatment in desperate cases. In the last stages of uræmia and eclampsia they are a most powerful agent in the struggle with death.

**A Fatal Case of Poisoning with Iodoform.**—In the *Presse médicale* for September 16th we find an abstract of an article from the *Revue médicale de la Suisse romande*, 1896, page 431, in which the author reports the case of a woman in good health, who died of iodoform poisoning. On the left leg there was a small varicose ulcer which had been dressed with iodoform powder. After this treatment tunctionation set in and the leg became red and painful, and at the end of eight days there was a generalized eruption which was manifestly due to the action of the iodoform. On the legs, the thighs, and the body the exanthema was like that of measles; on the arms and the buttocks it was characterized by a very diffuse scarlatinous redness. On the red ground of the eruption there was a great number of small milium vesicles which were detached and contained a lemon-colored liquid.

The patient suffered greatly; her face was red and tumefied, and there was profuse lachrymation, but no fever. The general condition rapidly became worse; the face grew pale and drawn; and in twenty-four hours two hundred and ten grains of albumin were found in the urine. Dyspnoea and weakness became progressive, and in twenty days after the onset of the symptoms death occurred. Some years before, says the writer, the patient had had a similar eruption, which had appeared after the employment of an iodoform dressing.

**Some Therapeutical Applications of Tannoform.**—A writer in the *Journal des praticiens* for September 12th states that E. Merck found that formaldehyde combined with tannin formed a product to which he gave the name of tannoform. This substance is endowed with remarkable therapeutic properties. Its astringent action certainly becomes developed in the intestinal tract, owing to its insolubility in the acid of the stomach. This fact indicates its employment in acute or chronic intestinal catarrh. Its antiseptic and astringent properties should lead to its trial as a topical antiseptic in wounds and atonic ulcers, in bromidrosis, in decubitus, in inflammation of mucous membranes other than the digestive mucous membrane (balanitis, erythrit, ozæna, etc.), and in the oozing eruptions in general. As an internal remedy, it possesses many advantages over tannin; its physiological properties scarcely differ from those of tannigen and tannalbin, but locally it is distinguished from these substances by special properties, and it exercises a remarkable topical action in many respects.

The drying and antiseptic qualities of this drug have been made use of in the treatment of operation wounds as a substitute for iodoform or for nosophene; also in old infected wounds and notably in atonic ulcers of the leg, against decubitus. In such cases, says the writer, it is one of the best topical applications, for it

has the great advantage of keeping the wound dry. It is useful also in ulcerating lupus of the nose after the fungosities have been scraped off, and it may be employed as a drying antiseptic on the uterine stump after myotomy by the extraperitoneal procedure. De Buck and De Moor have employed tannoform as an intestinal astringent and antiseptic in the diarrhoeas of infancy.

Tannoform has shown itself to be an excellent intestinal antiseptic and useful in constipation. Its action here is in every way comparable to that of tannigen and that of tannalbin; at present, however, it is impossible to say whether it is superior to these drugs, or to specify exactly its indications. It is especially to its local action that the writer desires to call attention. Its action is often so rapid as to require some prudence in its application. De Bück and De Moor state that they have not met with a single case of localized hyperidrosis which did not yield to applications of tannoform. In various eruptions in the oozing period the diseased surfaces rapidly dry up under the influence of this drug. As a dusting powder in the treatment of infected or non-infected wounds it may render great service. Over certain iodine compounds it has the advantage of being destitute of all odor, all irritating properties, and all toxicity. The following formulæ are recommended by De Bück and De Moor:

1. Tannoform.....	45 grains;
Zinc oxide.....	90 "
Vaseline.....	450 "
2. Tannoform.....	75 grains;
Talcum or starch.....	375 "

The amount of tannoform to be taken internally is from eight to fifteen grains a day, in four doses.

**Intestinal Indigestion.**—In the October number of *Mathews's Medical Quarterly* there is an article on this subject by Dr. J. N. Upshur, who devotes the first part to a detailed account of the definition, the varieties, the ætiology, and the pathology of this disease. In regard to the symptoms, he says, a serious difficulty is presented, as intestinal indigestion is complex, several fluids entering into the process.

The prominent symptoms depend upon the particular fluid deficient, or the way or avenue through which the faulty nervous stimulus may manifest itself. Therefore, a more rigid analysis is required, as well as a more careful and stricter process of exclusion.

It may be acute or chronic; the latter is the more common. The acute form may be brought about by imprudence in eating; the matter entering the intestine can not be physiologically disposed of, and pain, flatulence, borborygmi, fever, coated tongue, headache, and aching in the limbs rapidly develop and find a culmination in acute diarrhoea. An acute intestinal catarrh being the lesion, if this involves the common bile duct, interfering with the flow of bile into the intestine, the stools are clay-colored, slight jaundice exists, and the urine is loaded with lithates. Some of the symptoms are reflex, others are due to the absorption of sulphureted hydrogen into the system—thus the lassitude, aching in the limbs, and headache find an explanation. If the stomach participates, the symptoms are modified. These attacks are apt to recur at intervals. The intervals become shorter until a chronic intestinal indigestion is established. Food coming from the stomach is not properly prepared for absorption, decomposition readily takes place, and the prominent and significant symp-

tom is *pain* in the right hypochondrium or about the umbilicus, from one to three hours after eating. The pain is dull and gives a sensation of weight; it is not always fixed, and it is accompanied by tenderness on pressure. Tympany and borborygmus are present, and the individual experiences a sensation of fullness and distention. This is caused by the decomposition of the contents of the bowels. In acute indigestion the rapid formation of gas produces distention and spasm of the gut—acute colic. When the disease is chronic, this is not the case, but the sensation is one of uneasiness and dull, wearing pain. Constipation is commonly present, due to enervation of the intestinal walls and overdistention; the dejecta are too dry and sometimes covered with mucus from the development of chronic intestinal catarrh. Diarrhoea may alternate with the constipation, and particles of undigested food may pass off; the dark-green or black color of the stools indicating excess or perversion of bile; the slate color, its deficiency; the fatty matter, faulty action of the pancreas. The appetite is fitful and irregular, but not necessarily impaired. The patient awakes in the morning with a bad taste in the mouth, and the tongue is coated, relaxed, and swollen.

The nervous system is the first to suffer; disturbed function in the intestine, whereby the digestion and assimilation of fats are interfered with, impairs the nutrition of the nervous system, and results in depression of spirits, sleepiness, bad dreams, ringing in the ears, vertiginous sensations, pain in the head, confusion of thought, and loss of the power of application. Sometimes epileptoid attacks are traceable to intestinal indigestion; also sudden attacks of fainting and collapse, which are occasionally alarming. Melancholia sometimes exists. Cold hands and feet testify to a debilitated circulation; palpitation is present. Reflex irritation and impaired nutrition are responsible for heart complication. The urine is high-colored, of high specific gravity, and loaded with urates, and contains a large amount of sediment which is deposited on cooling. Sometimes albumin is found; errors in diet, like eating cheese or pastry, may cause it. Seminal emissions may occur. Faulty digestion, faulty sexual function, and consequent mental depression, reduce the subject to a condition of abject misery.

As the result of malassimilation, says Dr. Upshur, anæmia is an early symptom. Various skin affections, such as eczema, psoriasis, impetigo, etc., supervene to add to the distress of the patient. Consequent upon disturbed intestinal function is disturbance of the functions of the liver—lithæmia results with all its characteristic symptoms. Nutrition is still further impaired, and emaciation is pronounced, being specially noticeable in persons previously stout. Acute intestinal indigestion may terminate in a day or two and the patient be restored perfectly. Sometimes an obstinate diarrhoea is left behind. Chronic intestinal indigestion, if in children, is apt to persist until the diet is changed. In adults, if young, phthisis may have its inception here; in those more advanced, interference with so important a function may result more seriously, and the trouble may last for years. The influence of the intestinal disease upon the mind alters the whole character of the man. Everything seems out of joint; he becomes peevish, fretful, depressed, moody. It paves the way for some organic trouble, hepatic or renal, and the result of malnutrition closes the scene.

In the acute form, pain, flatulence, and diarrhoea

reveal the nature of the trouble. In the chronic form, the history of the case, the existence of the symptoms, digestive, mental, nervous, and cardiac, evidences of malnutrition, all these, with careful analysis of the symptoms pertaining to the liver, the pancreas, and the stomach, will enable us to reach a correct conclusion with little difficulty. It must be borne in mind, however, that the presence of fats in the stools, or a fatty diarrhoea, does not always indicate pancreatic disease; it has occurred in ulceration of the duodenum. The existence of glycosuria may be an aid to pointing out pancreatic disease.

If the disease is treated promptly and decisively, says the author, a cure may be effected, especially in the acute form. The chronic form is not so promising. Of supreme importance is implicit obedience on the part of the patient. Everything depends upon this and must be made subordinate to it. This being done, patience and perseverance may and will accomplish much. If the general health has become much impaired, the prognosis is more doubtful. Anæmia, debility, coexistent gastric dyspepsia, hypochondria, or a strumous diathesis in children, adds much to the gravity of the prognosis. If organic disease of the stomach, of the liver, of the pancreas, or of the heart exists the prognosis is very bad.

In the acute form, the first indication is to free the bowel from all irritant matter. A brisk mercurial purgative is preferable for this. The diet should be regulated, and pain relieved, if unbearable, at the beginning of the attack, by a hypodermic injection of morphine. If any intestinal catarrh exists, there is no remedy, says Dr. Upshur, superior to the phosphate of sodium in doses of thirty grains every two hours, given in half a teaspoonful of hot water. The tongue cleans promptly under its influence, and pain, soreness, and flatulence disappear. It should be continued for twenty-four or forty-eight hours. The diet should be simply milk or some suitable animal broth. In the chronic form the first indication is to put the patient upon a strict but nutritious diet, such a diet as will put the duodenum at rest as much as possible. In the beginning, an exclusive milk diet is best; if it does not suit the patient, it may be given skimmed, or if it still disagrees or is distasteful, the following preparation is palatable and beneficial in most cases: To a tumbler of sweet milk, add the white of an egg whipped up to a light froth and a wineglassful of limewater. Such farinaceous food as barley gruel or oatmeal may be combined with it. Animal broths may be allowed or some of the prepared meat essences. They stimulate the appetite and the secretion of the glands. When the demand comes for an improved diet, boiled fish, oysters, sweetbread, the white flesh of fowl once a day, and soft boiled eggs, one or two a day, may be allowed. Bread one day old, *sweet and light*, macaroni boiled in milk, and rice may also be allowed. Coffee is contraindicated, and tea should only be allowed when largely diluted with milk; cocoa (Phillips's digestible, which contains pancreatin) is a very pleasant drink. Butter is to be given in moderation. Wines are contraindicated, except under special conditions, to be determined for each individual. Mineral waters do good, *by change of air and scene*, and in those cases where little water is drunk, as a means of correcting constipation. Cheese, crabs, lobster, richly dressed meats, too much fat, pastry, and vegetables are to be avoided. The patient should be earnestly enjoined as regards the thorough mastication and in-

salivation of food, the harmfulness of haste in eating, and the necessity of a sufficient rest before and after eating. Tobacco chewing and smoking should be forbidden as impairing the character of the saliva and interfering with pancreatic secretion. Careful examination of the mouth should be made, and if the teeth are imperfect, artificial ones should be substituted for them. All causes which have combined to bring about the attack should be removed. A change to a cooler climate is advisable; early hours of sleep and regularity as to the time of meals and the interval between them should be earnestly advised. In overworked professional men, rest from all mental and physical effort should be insisted upon; massage and electricity are also very useful. The overtaxed child should be taken from school, and a careful effort made for his physical up-building. Sea bathing, properly regulated, is beneficial. If the condition of the patient is so extreme as to demand it, an artificially digested food may be given, such as peptonized milk.

Finally, continues Dr. Upshur, as to the administration of drugs, sulphuric ether has been recommended, as it possesses the power of stimulating the pancreas, given about an hour before meals. Good results follow the use of pancreatic extract and soda. Gastric digestion should also be cared for, as the more perfectly this function is performed the better the quality of the substances which go to the duodenum for the completion of digestion. When the liver is at fault, the bichloride of mercury in compound tincture of cinchona is very useful. This organ should also be stimulated to improved action by the administration of benzoate of sodium or ammonium, salicylate of sodium, etc. Atony of the intestinal walls, or deficient peristalsis, should be treated by the administration of strychnine given in full doses. This drug can not be too highly recommended for its power for good. Quinine in tonic doses is also available, and may be given in combination with it. If flatulence and abdominal distention are present, bismuth subnitrate is indicated in combination with benzosol or salol. In a case which recently came under the author's care he found great benefit from large doses (thirty grains) of the hyposulphite of sodium. Constipation is to be relieved by enemata or the administration of one of the bitter waters. He has found the Rubinat most satisfactory. Fluid extract of cascara is also useful, acting as it does as a tonic to the intestine and improving the muscular tone. Fowler's solution and tincture of nux vomica will be found useful; chloride of gold and sodium is a most valuable remedy; the only objection to it, which may be combated, is that it constipates. This property makes it useful in the diarrhoeal form. As soon as the patient's condition will admit of it, chalybeate tonics should be administered, backed up by such other remedies as will improve assimilation and nutrition.

**The Spontaneous Cure of a Malignant Tumor of the Bladder.**—Dr. K. Schuehardt (*Deutsche medizinische Wochenschrift*, 1896, No. 9; *Centralblatt für innere Medizin*, September 26, 1896) relates the case of a man, fifty-seven years old, who for four years had suffered from urinary disturbance. There was impeded urination with severe bearing down, at first without pain, but subsequently the urine was bloody for days together, and for six weeks it had been cloudy and offensive. There was a high degree of emaciation, and finally there was cough with expectoration. The patient

had a cachectic appearance, but, although the expectoration was abundant, no tubercle bacilli were found in the sputa.

Above the symphysis pubis there was a large, hard tumor over which the skin was only slightly movable. On examination with a catheter, the bladder was found decidedly contracted. The urine was loaded with pus and ammoniacal. On laparotomy, the right rectus muscle, for a hand's breadth above the symphysis, was found to be pervaded with tumor nodes showing a medullary, grayish-white cut surface, and it was adherent to the skin. The bladder had been converted into a firm lumpy tumor. On account of the numerous adhesions, further attempts at removing the neoplasm were abandoned, and the abdominal incision could not be closed entirely. The patient was very weak after the operation and had a good deal of pain, the expectoration was very abundant, and the temperature was elevated. At first the wound made good progress; then copious suppuration set in and the temperature fell and remained normal.

After nearly four weeks of almost monstrously abundant [*ungeheuer starken*] suppuration, in the course of which time no expulsion of pieces of tissue was observed, the flow of pus suddenly stopped almost entirely, and the general condition rapidly showed notable improvement. The urine was perfectly clear and free from albumin, although there had been no local treatment of the bladder whatever, and bimanual examination now showed that there was no noteworthy enlargement of the organ, but it was still somewhat indurated. After the healing of two fistulæ of the abdominal wall, caused by silk ligatures, had been accomplished by means of appropriate treatment, six months after the operation, the patient was dismissed perfectly cured. Three months and a half later his condition remained the same.

The author of the *Centralblatt's* summary, Dr. Reichmann, of Elberfeld, remarks that, in view of the extraordinary termination of this case, it is much to be regretted that there was no bacteriological examination of the pus or any microscopical investigation to establish the real character of the growth.

**Strontium Bromide in Epilepsy.**—In the *Lancet* for September 26th Mr. Anthony Roche calls attention to this treatment, which, he says, has afforded some relief in reducing, if not curing, the manifestations of the conditions in epilepsy. The number of cases is limited, and no general deduction can be drawn from them, but the author thinks they are sufficiently encouraging to induce others to give this bromide a trial. He states that he has used it alone or in combination with other bromides in four cases. The patients were not cured, but they obtained much relief. In all of the cases other bromides had formerly been employed and the combination of the strontium seemed to be more beneficial. It has long been noticed, he says, that a combination of bromides acts more favorably than any one of them alone. It should be impressed upon the patient that he must take the medicine for a long period, whether it has at first a beneficial effect or not. Mr. Roche thinks the bromide of strontium well entitled to further trial.

The treatment adopted by him, besides meeting any general indications, obtaining the best hygienic surroundings possible, and advising a strictly vegetable diet with milk, is to give twenty grains of the bromide of strontium with from five to ten grains of the bromide

of ammonium or sodium night and morning, largely diluted with water. The strontium is increased to one drachm twice a day rapidly if the smaller doses do not control the attacks, and if the patient does not complain of it. The majority of the patients, he says, took the strontium without any depression, but generally with the production of the acne rash on the face. Liquor arsenicalis added to the mixture controlled the rash and increased the appetite. This course in all the cases materially lessened the number of the attacks, and in eight of the cases there has been so far no return of them; that is after an interval of sixteen, twelve, eleven, nine, eight, eight and a half, five and a half, and four months respectively. As to the ultimate results of these cases, says Mr. Roche, it is impossible to judge, but the present improvement is so far encouraging.

**The New York Academy of Medicine.**—The programme for the last general meeting, on Thursday evening, October 15th, included the following titles: The Effects of Extrinsic Poisons on the Eye, by Dr. J. H. Claiborne; Infectious Diseases of the Eye, by Dr. C. J. Kipp; and The Visual Disturbances due to Nervous Diseases, by Dr. Ward A. Holden.

At the next meeting of the Section in General Medicine, on Tuesday evening, October 20th, papers are to be read as follows: Experience with the Treatment of Enteric Fever by Cold Tub Baths, by Dr. W. Gilman Thompson; and The Treatment of Enteric Fever by other Methods, by Dr. Morris Manges, who also will give a demonstration of the phenocendroscope.

At the next meeting of the Section in Obstetrics and Gynecology, on Thursday evening, October 22d, Dr. Bernard Gordon will read a paper on Gonorrhoea in Women, and Dr. John O. Polak will present one entitled Bladder Tuberculosis Successfully Treated by Keeley's Method of Direct Medication.

At the recent meeting of the Section in Laryngology, on Wednesday evening, October 28th, Dr. Thomas R. French will read a paper on Photography of the Larynx, and give a lantern exhibition and a demonstration of apparatus.

At the next meeting of the Section in Neurology, on Friday evening, October 30th, Dr. Ira Van Gieson will read a paper on The Relation of Toxic Agents in the Production of Nervous and Mental Disease.

**Proposed Medical Legislation in Vermont.**—The following is the text of a bill to create a State board of medical examiners in Vermont to which we briefly referred last week:

**SECTION 1.** The governor, with the advice and consent of the senate, shall appoint seven persons, residents in this State, who shall be graduates of a legally chartered medical college or university having the power to confer degrees in medicine, who shall constitute a board of registration in medicine. Such persons shall be appointed and hold office for terms of one, two, three, four, five, six, and seven years respectively, beginning with the first day of January, A. D. 1897, and until their respective successors are appointed, and thereafter the governor shall appoint, before the first day of January in each year, one person qualified as aforesaid, to hold office for seven years from the first day of January next ensuing. No member of said board shall belong to the faculty of any medical college or university. Vacancies in said board shall be filled in accordance with the provisions of this act for the establishment of the original board, and the person appointed to fill a vacancy shall

hold office during the unexpired term of the member whose place he fills. Any member of said board may be removed from office for cause by the governor. Said board shall consist of three allopathic, two homœopathic, and two eclectic practitioners.

**SEC. 2.** The members of said board shall meet on the second Tuesday of January next, at such time and place as they may determine, and shall immediately proceed to organize by electing a chairman and secretary who shall hold their respective offices for the term of one year. The secretary shall give to the State treasurer a bond in the penal sum of one thousand dollars, with sufficient sureties to be approved by the State auditor, for the faithful discharge of the duties of his office. The said board shall hold three regular meetings in each year, one on the second Tuesday of March, one on the second Tuesday of July, and one on the second Tuesday of December, and such additional meetings at such other times and places as it may determine. Five concurrent votes shall be necessary to effect a choice in the election of officers and in deciding such other questions as may come before said board.

**SEC. 3.** Any person twenty-one years of age and of good moral character, who is a graduate of a legally chartered medical college or university having power to confer degrees in medicine and said medical college or university being recognized, as determined by said board, shall, upon payment of a fee of ten dollars, be entitled to examination, and, if found qualified by five or more members of said board, shall be registered as a qualified physician, and shall receive a certificate thereof signed by the chairman and secretary. Any person refused registration may be re-examined at any regular meeting of said board, within one year of the time of such refusal, without additional fee. And thereafter he may be examined as often as he may desire, upon payment of the fee of ten dollars for each examination. Said board, after a hearing, may, by unanimous vote, revoke the certificate of any person registered by them, who has been convicted before a proper court of crime committed in the course of professional business.

**SEC. 4.** All fees received by the board under this act shall be paid by the secretary thereof into the State treasury once in each month. The compensation, incidental and traveling expenses of the board shall be paid from the State treasury on order of the State auditor. The compensation of members of the board shall be five dollars each for each day actually spent in the discharge of their duties, and three cents a mile each way for necessary traveling expenses in attending the meetings of the board, but in no case shall any more be paid than was actually expended. Such compensation and the incidental and traveling expenses shall be approved by the board and sent to the State auditor, who shall certify to the State treasurer the amounts due as in case of other bills and accounts that are approved by him under the provisions of law.

**SEC. 5.** The board shall keep a record of the names of all persons registered hereunder, and a record of all moneys received and disbursed by said board, and said records or duplicates thereof shall always be open to inspection in the office of the secretary of state. Said board shall annually report to the governor, on or before the first day of July in each year, the condition of medicine and surgery in this State, which report shall contain a full and complete record of all its official acts during the year, and shall also contain a statement of the receipts and disbursements of the board.

Sec. 6. It shall be the duty of the board to investigate all complaints of disregard, non-compliance, or violation of the provisions of this act, and to bring all such cases to the notice of the proper prosecuting officers.

Sec. 7. The examinations shall be, in whole or in part, in writing, and shall be of a practical character. They shall embrace the general subjects of anatomy, physiology, chemistry, pathology, practice of medicine, surgery, and obstetrics, and such other branches as the board may deem necessary, and shall be sufficiently strict to test the qualifications of the candidate as a practitioner of medicine.

Sec. 8. Any person who shall practise medicine or surgery under a false or assumed name, or a name other than that under which he is registered, or who shall personate another practitioner of a like or different name, or who, not being registered as aforesaid, shall advertise or hold himself out to the public as a physician or surgeon in this State, or appends to his name the letters "M. D.," or uses the title of doctor, meaning thereby a doctor of medicine, shall be punished by a fine of not less than one hundred nor more than five hundred dollars for each offense, or by imprisonment in jail for three months, or both.

Sec. 9. This act shall not apply to persons legally licensed or exempt under the provisions of former acts, or to commissioned officers of the United States army, navy, or marine-hospital service, or to a physician or surgeon who is called from another State to treat a particular case, and who does not otherwise practise in this State, or to prohibit gratuitous services.

Sec. 10. For the purposes of the appointment of this board, this act shall take effect upon its passage, and shall take full effect on the first day of January in the year eighteen hundred and ninety-seven.

Sec. 11. All acts or parts of acts inconsistent herewith are hereby repealed.

**The Treatment of Jaundice with the Root-bark of *Moringa Pterygosperma*.**—In the *Indian Lancet* for September 1st Mr. L. B. Dhargalkar, of Bombay, calls attention to a plant which he has used in the treatment of this disease. It is commonly known as Indian horse-radish or the drumstick tree. The root, the gum, the leaves, the flowers, and the fruit are all useful in medicine. The root has a strong, pungent odor and is said to have the flavor of horse-radish. When distilled with water, it yields an essential oil which is very pungent to the taste. The bark is rubefacient and is used externally by the poorer classes as a counter-irritant in chronic rheumatism. Some authors state that it is supposed to act as an emmenagogue and is used to produce abortion. The stimulant and pungent properties of the root-bark have been described by observers, but Mr. Dhargalkar thinks that no one has as yet mentioned its usefulness in the treatment of jaundice. He himself accidentally found that, if administered in proper doses, it was useful in that disease, and he has made several experiments with it.

The author relates the histories of eight cases in which he obtained satisfactory results with the tincture of moringa, the action of which was very rapid.

In regard to the toxic effects of the drug, the author states that he has had no opportunity to observe them, as it did not produce any unfavorable symptoms in any of the patients treated by him. In order to try its effects on the healthy system, he took on an empty stomach a drachm of the tincture in an ounce of water. It

tasted, he says, something like an infusion of bitter almonds and produced a sensation of warmth at the pit of the stomach for two or three minutes, but it did not produce any other effect.

The physiological action of the drug is, he says, still unknown to him, but he feels justified in calling the attention of the medical profession to its action in jaundice, and hopes that sufficient interest will be taken to promote investigations as to the true value of the plant in the treatment of this disease.

**Traumatol in Surgery.**—In the *Journal des praticiens* for September 26th M. L. Floersheim calls attention to a new substance which is likely to enter into ordinary surgical practice. It is a substitute for iodoform, the antiseptic qualities of which it possesses even to a greater degree, and has the advantage of being less toxic and being exempt from the disagreeable odor which is so unpleasant to patients. The conditions in which it may be employed are the general indications for all antiseptics. Its preparations are as numerous as those of iodoform and its employment is as simple. It may easily be incorporated in vaseline in the following manner:

Vaseline .....	75 grains;
Traumatol.....	15 "

This ointment may be employed in cutaneous affections or in the surgery of the eye. Gauze may be impregnated with traumatol as easily as with salol, iodoform, and boric acid. Traumatol pencils have been successfully used by certain surgeons in fistulous tracts and in endometritis; their preparation is as follows:

Traumatol .....	150 grains;
Pulverized gum.....	8 "

This is to be mixed with a sufficient quantity of water and glycerin. Traumatol may be mixed also with oil and collodion.

This new antiseptic, says M. Floersheim, is endowed with an active microbicidal power; it is inodorous; it does not give rise to erythema or to pruritus; it produces a perfect occlusion and hastens cicatrization; and its employment so far has given very encouraging results.

**The Employment of Calcium Carbide in Cancer of the Uterus.**—The *Revue internationale de médecine et de chirurgie* for September 25th contains a Paris thesis on this subject by M. Livet. According to the author, in the majority of cases the treatment of cancer of the uterus should be limited to palliation and the diminution of the intensity of the symptoms, as it is very frequently too late to attempt a radical cure; in fact, a radical cure can not be effected unless the disease is limited, that is to say, unless it is amenable to a partial operation according to one of the many procedures advocated. In the purely symptomatic treatment many remedies have been successively employed, but with fruitless results. Total hysterectomy has been advocated, but, although this operation radically suppresses the hæmorrhagic centre, relapses are the rule, and the pain is more violent after the operation than before. Partial success has been obtained by Pozzi's method, which consists in curetting followed by cauterization with the red-hot iron.

There are many methods of treatment for combating the fetid odor in these cases, but they are useless; the medicaments for combating pain are efficacious in the beginning, but their action rapidly decreases and finally almost entirely ceases. In view of the insufficiency of therapeutic measures, says the author, M. Guinard con-

ceived the idea of applying, in the treatment of uterine cancer, the coagulant action that acetylene gas exercises on the blood. He obtained the gas in its nascent state by putting calcium carbide into water, where it formed a deposit which proved to be lime. In accordance with M. Guinard's idea, M. Livet proposes using calcium carbide, not only in the treatment of uterine cancer, but also in that of other affections accompanied by rebellious hemorrhages, pain, and fetid odors, such as certain forms of fibroma and metritis. He reports eight cases, four of which demonstrate that the treatment with calcium carbide is always followed by an amelioration, whether in cancer of the breast, metritis, or epithelioma of the uterus.

According to the author, the application of this remedy offers no practical difficulty. In cases of cancer of the neck of the uterus, the vulva and the vagina should first be thoroughly washed and disinfected, and then pieces of calcium carbide should be placed in the inequalities of the tumor. If a calcium-carbide crayon is to be introduced into the cervical cavity, it must be done very rapidly, for when it comes in contact with the moist mucous membrane it produces a bubbling and nothing more is seen of it. In cancer of the breast the cavities are simply filled with pieces of calcium carbide.

As soon as the carbide comes in contact with the diseased parts acetylene is set free and escapes with a characteristic odor. In order to confine the acetylene, an ordinary dressing is used on the breast and tamponing is employed in the vagina. The action of calcium carbide is very rapid; the patient feels at once a burning sensation which lasts for an hour or two, and at the end of that time the pain, the discharge, and the fetid odor disappear. The clot which is formed by the coagulant action of the acetylene presents a temporary barrier, which is sometimes definitive, to the hemorrhage, and when the fetid discharge is dried up the nauseous odor disappears. When the tampon of iodoform gauze which confines the acetylene is removed the vegetations will be seen to be diminished in volume and covered with a grayish eschar which is easily detached with a blunt curette. It is not necessary to renew the applications of the carbide oftener than every four or five days, unless the hemorrhage should reappear on the day following the first application. If it is necessary to use the nascent lime to hasten the destruction of the neoplasm, the applications of the carbide may be more frequent. In all cases, the treatment, being purely symptomatic, should be continued until the fatal termination, which will be more or less retarded.

According to M. Livet, the symptoms caused by this treatment are few; in one case he observed diarrhoea and in another burns on the vaginal wall. Unfortunately, he says, the treatment is painful, and the burning sensation is very intense and occasionally persists for a long time.

**The Treatment of Painful Cystitis in Women by Vesical Curetting.**—The *Gazette hebdomadaire de médecine et de chirurgie* for September 24th publishes an article on this subject by M. G. Camero. The lesions of cystitis, he says, are in reality more frequently localized around the neck of the uterus and of the trigonum, and for quite a long time they are rather superficial. It is only in extreme cases that the condition of interstitial cystitis, which seems to be beyond therapeutical resources, becomes established. It has been observed that for a long time, even if there is intense pain, the mu-

cous membrane is not deeply involved and the rest of the bladder is scarcely diseased. In such cases, says M. Camero, amelioration is very distinct after vesical curetting. The operation is very simple and is preceded by thorough lavage of the bladder. For this a solution of boric acid is used to which one per cent. of a solution of corrosive sublimate of the strength of 1 to 1,000 without alcohol is added.

According to M. Guyon, says the author, this intervention does not completely cure the cystitis, but it renders the disease more amenable to other methods of topical treatment which before could not be tolerated.

M. Camero's conclusions in regard to this disease and its treatment are summed up as follows: 1. Painful cystitis is particularly frequent in women. 2. The measures to be resorted to should consist in the treatment of the uterus and its annexa and general treatment. 3. The local treatment of cystitis, although easy in light cases, becomes insufficient in pronounced cases. 4. Surgical treatment becomes necessary in cases in which the pain is intense. 5. Cystotomy, particularly colpocystotomy, should be reserved for very serious cases. 6. Very often recovery or a step toward recovery by means of local topical treatment may be obtained by curetting of the bladder through the urethra. 7. This operation is simple and easy; it does not require any complementary operation, and it gives excellent results.

**Poisonous Honey.**—In a paper read before the recent meeting of the American Pharmaceutical Association, says a writer in the October number of the *Pharmaceutical Review*, Mr. Lyman F. Kebler discussed poisonous honey. According to the author this honey has been known from ancient times and has been accounted for on very various hypotheses. Asia Minor has been the principal place of origin in the cases mentioned in literature, but the United States has not escaped. During the past year New Jersey has furnished eight cases. Pennsylvania and South Carolina have also contributed. The symptoms agree in the main features. Dimness of vision, vertigo, delirium, pain in the stomach and intestines, purging and vomiting, retching, and general symptoms of collapse are followed in the severest cases by death.

The poisonous article is sometimes marked by a dark, reddish color and a somewhat repulsive odor; at other times neither in appearance nor in odor would it awaken suspicion. The examination of various poisonous samples has revealed the presence of toxic principles. In South Carolina, honey that proved fatal in three cases out of twenty was found to be highly impregnated with gelsemine.

Honey used by persons poisoned not long since at Princeton, N. J., was examined by Mr. Kebler, who failed to find either alkaloids or inorganic poisons. Tests for andromedotoxin yielded uncertain results. It seems to be rightly suspected, since it is widely distributed through the family of the *Ericaceae* and is present in those plants that have been traditionally condemned by bee-keepers. *Kalmia latifolia*, *Andromeda* species, *Rhododendron* species, and various azaleas contain this principle.

Although it is not positively established by the chemical examination, Mr. Kebler regards the flowers of the *Ericaceae* as the probable source of trouble, and bee-keepers are advised to avoid regions where these flowers abound.

## Lectures and Addresses.

### LECTURES ON ANGINA PECTORIS AND ALLIED STATES.\*

By WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE VI.—PSEUDO-ANGINA PECTORIS (*continued*); THEORIES OF ANGINA.

II. TOXIC ANGINA.—The second division of functional or pseudo-angina embraces cases due to the abuse of tea, coffee, and tobacco, substances harmless in themselves, but which if taken in excess may disturb the action of the heart. My experience with this form is extremely limited. In tea or coffee drinkers I have never seen attacks of cardiac pain which could be called angina; though paroxysms of severe palpitation, with distress about the heart and gasping respiration, are not uncommon in nervous women much addicted to tea. Tobacco, as a rule, produces only slight and transient disturbance of the heart's action, but which may culminate in attacks of angina. When one considers how universal is the custom, the infrequency of severe heart symptoms in users of tobacco is remarkable. I pass months without seeing, in hospital or consultation work, an instance in which symptoms of any kind are due to it.

You all know, some of you have experienced, the acute toxic symptoms in beginning to use tobacco. The effects of the habitual use are very varied. To the large majority of persons the habit, in moderation, is harmless, to many it is beneficial. Among the injurious features those relating to the heart are perhaps the most important, certainly they are the most common. There are three groups of cases of so-called *tobacco heart*:

1. *The Irritable Heart of Smokers*.—Palpitation, irregularity, and rapid heart action are very common symptoms, particularly in young boys. They are often combined with dyspepsia; pain is not a special feature. There may be slight enlargement of the heart. It is a condition readily relieved by stopping the use of the weed. Disturbance of rhythm is the most constant effect of tobacco, and intermittence is more common than either slowing or hastening of the heart's action. Weakening of the vagus control is the more frequent, though in my own case the slightest excess in the use of tobacco causes intermission with slowing, not increase of the pulse-rate. An opposite effect—great rapidity with feebleness of impulse—is more common, and may develop suddenly in an habitual smoker.

2. *Heart Pain*.—Sharp shooting pains about the heart are not very uncommon in persons who smoke or chew too much. They may occur alone without disturbance of the cardiac rhythm or without the intensity

and associated features of an attack of tobacco angina. The following is a good illustrative case:

I. B., aged twenty-nine years, seen March 24, 1896, complaining of pain in the region of the heart just below the nipple. The first attack was four or five years ago, and it has recurred at intervals ever since. Shortly after the onset his physician suggested that it might be due to tobacco; and when he gave up smoking the attacks disappeared altogether. Since he resumed the habit they have recurred, and for the past year he has had them more frequently. The attacks occur at night, just after he has fallen asleep. He is awakened with a severe pain in the region of the heart, which almost takes his breath away, and makes him cry out at once. It rarely lasts more than a minute or two. The heart's action is not increased. He never has had any sweating, and does not change in color, nor do his hands and feet become cold. He has never had any pain down the arm. It is always of the same character, sharp and stabbing, just below the nipple, and is intense enough to cause him to cry out. He has had as many as four or six attacks in the twenty-four hours. In the daytime the pain is not so severe, and the spells are more transient. He has never had an attack following exertion, and neither emotion nor errors in diet have any influence upon them.

He was a member of a very nervous family. He was himself a healthy, vigorous man. He had smoked from his boyhood three or four strong cigars, and when traveling, five or six cigars a day. He felt himself that the tobacco was responsible for the pain. He was a healthy-looking man, a little pale. The pulse was 76, regular, and without increased tension. The apex-beat was in normal situation; the heart sounds were everywhere clear. The second aortic was perhaps a little accentuated. There was no pain on pressure, and no hyperæsthesia.

He was advised to stop smoking altogether.

3. *Tobacco Angina*.—I have seen but two cases in which severe paroxysms of cardiac pain occurred in habitual smokers.

Dr. —, of —, aged thirty-five years, consulted me April 13, 1891, complaining of severe pains in his chest and of numbness in the left arm. The patient has a very gouty history on both sides. He has been a hard-working practitioner, has been a moderate drinker, and has used tobacco to excess, both smoking and chewing. Four years ago, when he had been smoking very heavily, he had an attack of pain about the heart and down the arm, for which he consulted Dr. Pepper. He had very little trouble again until six or eight months ago, when the attacks recurred. He then consulted Dr. DaCosta, who said that he was gouty and without organic disease of the heart. Lately the attacks have been very severe, chiefly under the left margin of the sternum and reaching down the arm, which becomes numb and tingles. He has never had an attack in which there was a sense of impending dissolution. The patient was a healthy-looking man, the pulse was 78, the tension a little plus, but there was no sclerosis of the arteries. The examination was negative, with the exception that the aortic second sound was perhaps a little sharper and clearer than normal. He was told that he had no heart disease, and he was urged to live a temperate life, to give up tobacco, and ordered ten grains of iodide of

\* Delivered to the Post-graduate Class, Johns Hopkins Hospital.

potassium three times a day. After seeing him the first day I dictated the following note:

"In this case the gouty history and the accentuated second sound are perhaps suggestive of true angina. On the other hand he has been a very heavy smoker, is evidently nervous and worried about his condition, both of which factors must be taken into consideration."

I have seen this patient at intervals during the past five years. He lays very great stress upon tobacco as the cause of the attacks, and any indulgence is apt to be followed by severe pain.

On February 17, 1894, in a letter he laid stress again upon the part played by tobacco; in a letter received recently he gives a very satisfactory account of himself, though he still smokes, and still has attacks. There is a feature in the attacks in this case upon which Huchard lays a great deal of stress in tobacco angina—namely, the occurrence of certain nocturnal spells almost like syncope. This patient states in the recent letter that "the strangest symptom of all is that just as I lose myself, and am about to drop to sleep, and often just after losing consciousness, I choke, sit up quickly, and feel for the moment as if 'the game was up.' There is no pain, no excitement of the heart, and yet this often occurs after having a choking fullness and distention in my throat, as if I was trying to force a great volume through a small space." He adds, "Sudden inhalations of tobacco smoke still give me pain about the heart, lasting for several minutes."

T. W., aged forty-five years, seen with Dr. Goldsborough June 12, 1895.

The patient was a very vigorous, healthy-looking man, and has enjoyed uniformly good health. In November, 1894, he had influenza and was wretched for two months after it. He had been a heavy smoker since his fourteenth year. Some years ago he gave up the habit for twelve months, as he had attacks in bed in which he felt as though the heart had stopped and he would have to jump out of bed and gasp for breath. He got well and has smoked heavily ever since.

On the 6th of January he had a sudden, severe paroxysm, to which he attributes his present nervous condition. He had been smoking on an average twelve strong cigars a day. The attack began with a peculiar feeling in the chest, not exactly pain, but great distress. He turned pale, belched gas constantly, perspired, was cold, could not lie down, and felt as though he was going to die. He had no agonizing pain, but he felt a sense of terrible oppression, and had numbness in both hands and wrists. The heart's action during this attack was scarcely perceptible, the pulse very feeble and fluttering. It lasted altogether two or three hours, and alarmed him very much. For several days afterward he felt prostrated and weak, and for a month he had a sort of faint feeling, particularly after eating. These faint attacks have distressed him very much. They would come on at intervals and he would turn pale and sweat profusely. He never has actually fainted in them, but one day in the barber's chair he very nearly lost consciousness. They recurred for about two months after his severe attack. He has been very nervous and uneasy about himself, and has been greatly worried. He has stopped tobacco since January 6th.

The patient was a robust-looking man of good color. There was no arteriosclerosis. The apex-beat was within the nipple line, visible, readily felt, of normal intensity. There was no increase in the cardiac dullness. The heart sounds were clear, and there was no accentuation of aortic second. There was no enlargement of either liver or spleen.

Up to April 17, 1896, when last heard from, this patient had had no return of the attacks, and had been quite well.

As my experience of this form has been so limited, I will read you Huchard's statements as to the chief characters of tobacco angina:

1. "Angina pectoris due to tobacco assumes often the vasomotor type (extreme pallor of the face with vertigo, contraction of the pulse, tendency to syncope, præcordial anxiety with or without pain, chilling of the extremities, cold sweats).

2. "The attack of angina is often associated with other manifestations of nicotine poisoning: vertigo, ringing in the ears, dysphagia, headache, a sense of suffocation and dyspnea (nicotine asthma), sensations of general weakness, of cerebral confusion, of spinal hyperæsthesia, troubles of vision, etc. These symptoms may be dissociated from the paroxysms and observed separately.

3. "Those suffering from tobacco angina show, almost always, apart from or during the course of their attacks, disturbances in the heart's function: slowing with enfeeblement of the heart's beat, tachycardia or bradycardia, intermissions, arrhythmia, palpitation, tendency toward lipothymia or syncope, attacks of palpitation with extreme irregularity of the heart (*folie cardiaque, delirium cordis*).

4. "The attacks of angina are often very painful and complete in their intensity and in the radiation of the pains. But it is in angina from tobacco that one sees particularly the imperfect and abortive forms, consisting of dyspnea with slight præcordial anxiety, or simply of a little sense of uneasiness behind the sternum, with the sensation of stopping of the heart and the fear of impending death.

5. "Angina from tobacco shows generally spontaneous paroxysms; they may also be produced by exercise or exertion. It has then the clinical characters of angina from coronary artery disease.

6. "The paroxysms of *functional* tobacco angina due to spasmodic contractions of the coronaries disappear rapidly after the complete stopping of tobacco, a clinical feature common to almost all the symptoms of tobacco poisoning without lesions.

7. "This is not true of the paroxysms of *organic* tobacco angina due to organic contraction of the coronaries (through nicotine arteriosclerosis). This form is more resistant; it disappears but slowly, or may be permanent; it is worthy of treatment with iodide of potassium.

8. "There exists another form of stenocardia, the

most benign of all; it is due remotely but not immediately to nicotine; it follows dyspepsia produced by the abuse of tobacco; it is cured by the removal of tobacco and the disappearance of the dyspepsia."

It would be impossible to discuss, even briefly, all of the theories which, from time to time, have been offered in explanation of this remarkable group of symptoms. Huchard has tabulated sixty-one opinions under six main theories! Under these circumstances it will be wise to start out with the statement of a generally accepted fact—viz., that in an immense proportion of all cases *angina pectoris vera* is associated with disease of the coronary arteries and of the myocardium. This, you will recall, was Jenner's original suggestion, which he enounced in the letter I read to you in Lecture I. Very shortly after the appearance of Heberden's paper the first reports of coronary-artery disease in angina were made by Fothergill—the great Fothergill, whose friendship with Rush and whose interest in the medical affairs of the American colonies endeared his name to the profession on this side of the Atlantic. In the first case which he reports there is no note upon the coronary arteries, but "on the outward muscular part (of the heart) near the apex was a small white spot as big as a sixpence, resembling a cicatrix," evidently a patch of fibroid myocarditis. In another case (which seems really to have been one of *angina sine dolore*) the patient, who had a difficulty or incapacity to walk up a moderate ascent, died in a sudden transport of anger. John Hunter, who made the dissection, found "the two coronary arteries, from their origin to many of their ramifications upon the heart, were become one piece of bone."\* The older reports, which corroborated the opinion of Jenner, are to be found in Parry's monograph; while the full statistics on the question have been collected with great pains by Huchard. In a supplementary chapter to his work you will find a summary of 145 autopsies in cases of angina, gathered from the literature. In 17 cases there was mention only of a lesion of the coronaries without further specification; of 128 there were 68 with lesions of both coronary arteries, 37 of the left vessel, 15 of the right, and in 12 the seat of the lesion was not stated. In the 128 cases obliteration or stenosis of the vessels had occurred, and of these in 121 there was atheromatous narrowing or thrombosis, in 5 embolism, and in 2 compression. Fatal cases are on record in which the coronary arteries have been found normal; most of these are instances of adherent pericardium or valvular disease. There are also fatal cases of tobacco and post-febrile angina in which the anatomical condition is stated to have been negative. Nothing is easier than to overlook myocardial changes, particularly in the older methods of examination, and a heart may present extensive fibroid disease with obliteration of arteries, which to the untrained eye looks

healthy, or which may not show any coarse lesions of the aorta, or of the main branches of the coronary vessels. Or again, with Krehl's method of serial section a heart apparently normal may show extensive myocarditis, with changes in the smaller arteries. Spasm of the coronary arteries has been invoked to explain the sudden death in these cases, but it is much more likely that changes of a serious nature were overlooked (as from personal experience I know they often are) in the ordinary methods of examination. Ischemia, a condition in which the heart muscle is imperfectly supplied with blood, is the main factor in all coronary lesions, whether narrowing of the orifices of the arteries, atheroma of their walls, or thrombosis or embolism of their channels.

In seeking to explain the relation of the arterial and myocardial changes to the symptoms of angina we pass at once into the region of speculation. On turning to the therapeutical indexes and finding a list of twenty or more drugs recommended in a given disease you may be quite safe in concluding that our knowledge of the treatment of the affection is, to say the least, imperfect; and so, when you read the tabular list of the theories of angina, covering nearly four pages of Huchard's *Traité*, you may feel assured that the last word has not yet been said upon the subject.

The view which is based most directly on the coronary-artery disease is one which, as I shall tell you, dates really from the early part of the century, and finds its explanation in the remarkable phenomenon known as *intermittent claudication*. Bouley,\* Sr., the celebrated French veterinarian, described an affection in the horse, in which, after being driven for fifteen or twenty minutes, the animal stops, the hind legs get stiff, and soon it is unable to stir. It may fall down, and apparently be in great suffering. In from half an hour to an hour it will recover and will go on comfortably for another fifteen minutes, and then an attack recurs. In such cases, post mortem, the artery of the affected limb has been found blocked with a clot, or, when both hind legs have been involved, the abdominal aorta has contained a thrombus.

Charcot, while an interne in the service of Rayer, described in man a condition corresponding to this intermittent claudication in the horse. He says† that one day a patient in the service told him that he was not able to walk for more than a quarter of an hour without being taken with cramps in the legs. After resting a while he would get better, and was able to resume his walking, and then a crisis recurred. At the autopsy he found a ball encysted in the neighborhood of the iliac artery, and a traumatic aneurysm which had obliterated the artery in its lower part. The circulation was carried on by collateral channels, which

\* *Medical Observations and Inquiries*, vol. v, 1774.

\* *Nouveau dictionnaire pratique de médecine, de chirurgie et d'hygiène vétérinaires*. Tome deuxième, pp. 540. Bouley and Renault, 1856.

† *Leçons du mardi*. Tome i, p. 45.

were ample to maintain the nutrition while the patient was quiet, and for a short period during exertion, but after a time, when the limbs were fatigued by the movements, the quantity of blood which reached them was insufficient, causing a relative ischemia, with tingling, cramps, and impossibility of walking. He refers to the fact that the condition is often preliminary to gangrene, and narrates a case in which one of his patients with the affection had his leg amputated for gangrene.\*

The credit of pointing out the analogy between this condition and angina pectoris, which is ascribed usually to Potain (1870), but which is maintained by Weber † to have been clearly shown by Brodie, in 1816, belongs in reality to Allan Burns, whose *Observations on Some of the Most Frequent and Important Diseases of the Heart*, 1809, is a well-known storehouse of interesting facts. Since, so far as I know, this distinguished writer's connection with this supposed new theory has not been pointed out (except in the second edition of my *Practice*), I will read to you in full what he says on the subject: "Such a state of the arteries of the heart [referring to atheroma] must impair the function of that organ. It has been long known, that although the heart is always full of blood, yet it can not appropriate to its own wants a single particle of fluid contained in its cavities. On the contrary, like every other part, it has peculiar vessels set apart for its nourishment. In health, when we excite the muscular system to more energetic action than usual, we increase the circulation in every part, so that to support this increased action the heart and every other part has its power augmented. If, however, we call into vigorous action a limb round which we have with a moderate degree of tightness applied a ligature, we find that then the member can only support its action for a very short time, for now its supply of energy and its expenditure do not balance each other; consequently, it soon, from a deficiency of nervous influence and arterial blood, fails and sinks into a state of quiescence. A heart, the coronary vessels of which are cartilaginous or ossified, is in nearly a similar condition: it can, like the limb begirt with a moderately tight ligature, discharge its functions so long as its action is moderate and equal. Increase, however, the action of the whole body, and along with the rest that of the heart, and you will soon see exemplified the truth of what has been said, with this difference, that as there is no interruption to the action of the cardiac nerves, the heart will be able to hold out a little longer than the limb.

"If a person walks fast, ascends a steep, or mounts

a pair of stairs, the circulation in a state of health is hurried, and the heart is felt beating more frequently against the ribs than usual. If, however, a person, with the nutrient arteries of the heart diseased in such a way as to impede the progress of the blood along them, attempt to do the same, he finds that the heart is sooner fatigued than the other parts are, which remain healthy. When, therefore, the coronary arteries are ossified, every agent capable of increasing the action of the heart, such as exercise, passion, and ardent spirits, must be a source of danger."

He discusses also whether the paroxysm was dependent on a state resembling paralysis, or on a spasmodic contraction of the fibres of the heart. He hardly thinks that the view of spasm is corroborated by any analogous facts in the animal economy. He says: "Do we ever, after the operation for aneurysm, see the muscles in a state of rigid action; or, when we apply the tourniquet only so tight as to impede the circulation, do we ever observe that the member is affected with spasm? In both cases we witness an induction of an extreme degree of debility, and we hear the person complaining of an unusual painful feeling in the limb, but still its muscles are in a state of inactivity. If these be the phenomena resulting from a deficiency of arterial blood in the muscular system in general, why should the heart be an exception? We know that this organ is principally composed of muscle, and we have therefore reason to believe that it is regulated by the same laws which govern other muscles."

I will read you this intermittent claudication theory as formulated by Potain, in 1870, and you will see how completely the distinguished clinician of *La Charité* has been anticipated by the old Glasgow professor: "If one considers the painful sensations, the disorders of the cardiac action, which constitute an attack of angina pectoris; if one but remembers that these paroxysms occur always after fatiguing movements, muscular efforts, or emotional disturbances—that is to say, under conditions in which the heart is compelled to contract more frequently and to do more work: if one considers finally, that repeatedly some narrowing or ossification of the coronary arteries has been found in the bodies of victims of this disease; if one considers these facts, it will appear in every way probable that the heart does not escape from the common law, that it also becomes rapidly exhausted when its arteries can no longer give it the quantity of blood necessary for its increased activity; and that then it becomes the seat of painful disorders, just as in the case of the muscles of the lower extremity. Herein lies a principle which may be briefly expressed as follows: The symptoms caused by ischemia become exaggerated whenever the diseased organ becomes active, because of the increased quantity of blood which this activity demands."\*

It is easy to suppose that a narrowing of the orifices

\* Charcot seems to have felt hurt that his communication on so remarkable a phenomenon had not received any attention. He says: "Je n'ai pas encore rencontré, chose singulière, car mon mémoire de 1855, présenté à la Société de biologie, n'est pourtant pas écrit en chinois, il me paraît écrit en français, presque en bon français, je n'ai pas rencontré, dis je, un seul médecin qui ait tenu compte de mes observations."

† *American Journal of the Medical Sciences*, May, 1894.

\* Quoted by Huchard.

of the coronary arteries, or of the lumen of a main branch, can bring about conditions most favorable for the production of this intermittent claudication—*i. e.*, a state in which, so long as the heart is acting quietly, sufficient blood reaches its muscle; but if called upon to act more forcibly, by exertion or emotion, the larger supply, then needful to maintain the nutrition, might not be forthcoming, with the result of a relative ischæmia and disturbance of function.

What is the condition of the heart muscle in this ischæmia? Is it likely to be the same in the narrowing of atheroma and in the blocking from thrombosis and embolism? How shall we account for the remarkable disparity between the incidence of angina pectoris—a rare affection—and the incidence of coronary-artery disease—an everyday degeneration in persons above the age of sixty? With what special conditions is the pain associated and what relation have the pains of pseudo-angina to those of the angina vera? What part is it probable that vasomotor changes play in the process? These are among the questions which must be asked and answered before we can accept the intermittent claudication or, indeed, any other theory. We may discuss these points under three heads: the state of the heart muscle, the seat and cause of the pain, and the vasomotor changes in the disease.

(To be concluded.)

## Original Communications.

### ON THE APPLICATION OF THE SERUM DIAGNOSIS OF TYPHOID FEVER

TO THE REQUIREMENTS OF  
PUBLIC HEALTH LABORATORIES.\*

By WYATT JOHNSTON, M.D.,

MONTREAL,

BACTERIOLOGIST TO THE BOARD OF HEALTH FOR THE PROVINCE OF QUEBEC;  
PATHOLOGIST TO THE MONTREAL GENERAL HOSPITAL.

GREAT interest attaches to Widal's important communication to the effect that the serum of persons suffering from typhoid fever, even in the early stages, is capable, when mixed with a pure culture of the typhoid bacillus in bouillon, of arresting the active movement so characteristic of this organism and causing the bacilli to agglutinate into clumps resembling zoogloea. The serum of typhoid convalescents and immunized animals had been shown by Pfeiffer, Durham, and Gruber to possess this property. But Widal has certainly been the one to demonstrate its great clinical value. With the serum of an undoubted case of typhoid fever we are able to apply what appears to be the most conclusive of the tests at our disposal in deciding whether a given organism is really the typhoid bacillus or not. On the

other hand, with a culture of the genuine typhoid bacillus, we are able to decide whether a doubtful case is or is not typhoid fever.

Although the test is so recent in origin, those who have tried it appear practically unanimous as to its being of great delicacy, and, in particular, the negative results which it furnishes are of nearly as much practical value, something which can scarcely be said of the routine bacterial tests for tuberculosis.

Widal's original method was to obtain the serum from the vein of a patient's arm by means of a sterilized syringe, decanting the serum after it had separated and adding it to bouillon culture of typhoid bacilli. This was then placed in the incubator, and showed, after several hours, a flocculent precipitate composed of the immobilized and agglutinated bacilli and a clearing of the upper part of the fluid. This was found by Widal to be characteristic of typhoid blood. The blood in other febrile disorders, such as malaria, typhus, tuberculosis, pyæmia, etc., as well as the serum of healthy persons, were found to have no power of producing this phenomena when mixed with typhoid cultures. Those who have repeated Widal's experiments have also been able to confirm his statements that the colon bacillus does not give this reaction with typhoid blood.

Widal was fortunately led to simplify the method materially by taking a few drops of blood from the finger tip, and as soon as the serum was separated from the edge of this mixing it with a drop of actively mobile typhoid culture, whereupon the reaction could be satisfactorily observed under the microscope and was usually complete in a few minutes.\* Dieulafoy testifies to the remarkable accuracy of the test and its value in diagnosing obscure cases.

My attention was first directed to the test through having been consulted by physicians as to the nature of suspected cases of typhoid, and my experience has been thoroughly in accord with that of Widal and others as to its great value as an aid to clinical diagnosis.

As the reaction appeared to depend probably upon the presence of some substance analogous to the ordinary toxins, and as many of these preserve their characteristics in a dry state, it naturally occurred to me that this might be true of the substance producing the serum reaction. The advantage of being able to operate with a dried substance was obvious, especially with reference to the possible application of the method to the rapid bacteriological diagnosis of typhoid fever in municipal laboratories, just as is now done in the case of diphtheria, and my observations have been made with this end in view.

Instead of taking the serum as soon as it exuded, I allowed the drop to dry, and found that upon moistening it subsequently the solution obtained was just as

\* Read before the American Public Health Association, at Buffalo, N. Y., September 17, 1896.

\* This plan of observing the reaction directly under the microscope had been published by Gruber and Durham some months previously.

efficacious as the pure serum for the diagnostic purposes of the test.\*

This power appears to remain practically unimpaired even after the blood has been allowed to dry for many days. My experiments upon how long the blood will continue to react when in this dry state are not yet finished, but blood drops dried for from two to four weeks still give the reaction.

In this manner I have tested the blood of ten patients suffering from undoubted and typical attacks of typhoid. The reaction was obtained conclusively in every instance. In eight cases the loss of mobility and the agglutination was complete in from two to fifteen minutes. Of the two others, one, in a very early stage of the disease, required thirty minutes for the completion of the reaction, while the other in a very late stage, following a relapse, required one hour.

**Control Cases.**—The blood of ten other hospital patients, as well as a number of healthy individuals, was next tested, and in no single instance was the reaction obtained. Occasionally a pseudo-reaction with some agglutination was observed within a few minutes of the mixture of blood solution and culture, but some movements of translation (wandering through the field) always persisted on the part of isolated bacilli, and these gradually increased in number and activity till, in an hour or two, lively motion was resumed, and was found to be still present on the following day and, in some instances, where it was followed up, at the end of a week. With the typhoid bloods nothing but the oscillating or "Brownian" movements were seen, as a rule, though where the proportion of serum added was very small peculiar revolving and tugging movements, apparently due to the action of the flagella, could be made out, movements from one part to another of the microscopic field being, however, completely abolished.

In two doubtful cases examined for diagnosis the results were negative. In one of these the malaria plasmodium was subsequently detected. The other left the hospital before the diagnosis was cleared up, but her temperature had remained normal for two weeks, and her only symptoms were persistent headache and giddiness. One of the control cases, examined with negative results, had a history of typhoid two years previously.

[In making a communication upon this subject before the American Public Health Association at Buffalo, N. Y., on September 17, 1896, I subjected the method to what I considered to be a fair practical test as to its applicability to public health purposes. I left instructions for Dr. D. D. McTaggart, resident pathologist, to forward by post to my destination, after I had left

Montreal, a letter containing dried blood drops from several cases of undoubted typhoid fever and also dried blood drops for control from other hospital cases, preferably patients suffering from febrile conditions, but making sure that they had not had typhoid recently. All these blood drops were to be numbered and a key giving the clinical diagnosis in each case placed within a separate sealed envelope.

I left Montreal September 13th. Samples of blood from six patients were collected, and forwarded as directed on September 14th. On September 16th the letter was delivered unopened at Buffalo, N. Y., to Dr. Bissell, the City Bacteriologist for Buffalo, who kindly took charge of the key. At the end of an hour spent in examining the specimens, I wrote my diagnosis upon the outside of the sealed envelope. It will be seen from the subjoined signed statement, which Dr. Bissell kindly made at my request, that the results were perfectly in accord with the clinical diagnosis in each case, while the specimens, which were then examined by a number of competent bacteriologists, showed that good objective grounds existed for arriving at the conclusions given.

*Statement by Dr. McTaggart, Resident Pathologist, Montreal General Hospital.*—The samples of blood were mailed to Dr. Johnston one day after he had left Montreal. Dr. Johnston had no knowledge of the contents of the "key," and no private means of knowing which of the numbers referred to typhoid and which to non-typhoid blood. (Signed.) D. D. McTAGGART.

*Statement by Dr. Bissell, City Bacteriologist, Buffalo, N. Y.*—Buffalo, September 16, 1896: Received to-day from Dr. Wyatt Johnston a sealed letter, mailed in Canada, with postmark, "Montreal, September 14, 1896." This was opened by me and found to contain (a) six glass cover slips, numbered from 1 to 6, with a drop of dried blood on each, and (b) also a sealed envelope marked "key." Received from Dr. Johnston, after examining the blood by the (Widal) serum diagnostic test, the following report: No. 1, typhoid; No. 2, typhoid; No. 3, typhoid; No. 4, not typhoid; No. 5, not typhoid; No. 6, doubtful, probably not typhoid. The key was then opened by me and the clinical diagnosis from all cases found as follows: No. 1, typhoid; No. 2, typhoid; No. 3, typhoid; No. 4, malaria; No. 5, enlarged glands of neck; No. 6, heart disease.

(Signed.) WILLIAM E. BISSELL.

It will be noticed that a qualified though correct opinion was given at the time of my making the report in one of the negative cases (No. 6). This doubt was owing to the fact that it was the last specimen examined, and that a partial agglutination appeared to take place at first, though motion was not abolished. Subsequent examination some hours later showed such lively motion that I should have had no hesitation in declaring it not to be typhoid had the circumstances permitted that much delay before an opinion was given.]

\* Since writing the foregoing I have been able to obtain fuller accounts of Widal's work than were at first available, and find it stated by him (*Bulletin medical*, 12 août, 1896, p. 267) that dried serum, and to a lesser extent dried blood, are capable of furnishing the reaction. This circumstance does not appear to have been hitherto utilized practically.

A ready means of diagnosis in typhoid fever is something which has long been desired by sanitary officials. The medical profession is proverbially lax with regard to the notification of typhoid cases, and we may assume that this neglect is in part due to the want of any adequate *quid pro quo* in return for such notification. Probably the assistance derived from a prompt bacteriological diagnosis or even corroboration of diagnosis in the early stages of typhoid will lead to the more uniform reporting of cases. Besides distinguishing typhoid from such well-characterized diseases as tuberculosis and malarial disease, this test may also be expected to clear up the mystery which surrounds those doubtful cases of so-called bilious fever, remittent fever, gastric fever, typho-malarial fever, etc., which are so common in times and places where typhoid is prevalent, and rare in the absence of typhoid, at least in temperate regions which are free from malaria.

Those who are called upon to investigate epidemics of typhoid are much perplexed by the large number of cases of ill-defined and transitory fever occurring among those personally exposed to the infection, and the impossibility of coming to anything like a definite conclusion upon the evidence hitherto obtainable as to whether these are to be regarded as cases of abortive typhoid or not. In my own experience, such cases have usually equaled or outnumbered the cases where the symptoms justified a definite diagnosis.

I may add a few words with regard to technic. I use a dry lens of about one-fourth-inch focal distance. The dry blood drop is partly dissolved with germ-free water and a drop of the solution obtained is placed upon a cover glass which has just been passed through a flame and mixed with a drop of a typhoid bouillon (a watery suspension of an agar culture also answers very well). This is placed over a hollow cell sealed by vaseline. I control the examination by comparing it with a blood drop from an undoubtedly typhoid case and also with normal blood. It is also advantageous to place a minute drop of the blood solution upon the cover slip alongside the mixture of culture and serum, so as to satisfy one's self in negative cases that the blood contains no motile bacteria. Uniformity of temperature is the chief detail to be attended to, as the agglutination does not take place so well if the movements are sluggish. A hot-water dish filled with warm water forms a cheap and convenient substitute for an incubator, and a simple warm stage made of a sheet of copper is also useful. In a well-warmed laboratory, however, the use of these adjuncts is unnecessary. Hollow cells are convenient, but not indispensable. For collecting the blood drop any smooth surface suffices; cover glasses or slides have the advantage of being clean and sterile, but I have found ordinary writing paper or smooth cardboard most convenient, as it could be more easily labeled or forwarded. The swabs used for diphtheria outfits will answer, but the presence of extraneous substances, such

as fibres, was found annoying. The presence of blood pigment is rather an advantage, as it enables the drop to be more easily focused. The small fibrin particles of clot sometimes bear a superficial resemblance to the islets of agglutinated typhoid bacilli, but are readily distinguished from them by the presence of leucocytes in their meshes.

One advantage of having the blood dried is that it insures it against contaminating growth occurring during shipment. In case any doubt as to the reaction exists at first, it will usually be dispelled by watching the preparations for some hours, or, if necessary, for a day or two. This permits a decided and progressive increase of motion in non-typhoid cases and allows the more perfect agglutination in the genuine ones.

The one indispensable factor is perfect purity of the culture. The one which I use was kindly forwarded me by Mr. J. J. Mackenzie, Bacteriologist to the Ontario Provincial Board of Health, and was stated to have come originally from the Berlin Hygienic Institute. It grows typically on gelatin, potato, bouillon, agar, and milk; reacts typically with litmus agar, produces no indol or gas, and shows the motility and staining reactions characteristic of the Eberth bacillus.

I have made this communication because the method here suggested seems better adapted than those hitherto employed for bringing this test within the range of ordinary public-health laboratory work and enabling it to be dealt with, if I may so express it, in a wholesale manner.\*

\* Drying the blood as a preliminary step has enabled the Board of Health of the Province of Quebec to offer to the medical profession here a free public service of typhoid diagnosis by the serum method similar to that which is followed in diphtheria. Outfits consisting of a folded and sterilized piece of paper, in which the blood drop is sent inclosed in a suitable envelope, are placed in convenient depots. In case of negative results an additional sample taken by collecting a few drops of blood in a small glass tube is examined, but this extra precaution is seldom necessary. As to the degree of accuracy which this application of the test may afford, it is too early to speak positively. From my experience hitherto I am inclined to believe that it will compare not unfavorably with those obtained in the cases of diphtheria and tuberculosis. In one case the reaction was present on the fourth day

roughly classified with regard to their mental characteristics alone, as mania, melancholia, dementia, or still further particularized by the names which defined their periodicity, or the crisis at which they appeared, or the element of hereditary predisposition; although in a few exceptions, notably hepatic and rheumatismal insanities, the somatic element has been recognized.

The defect of most classifications of an assigned ætiology is that no serious attempt is made to satisfactorily connect the alleged cause with the symptoms and satisfactorily explain them. Granted that intrinsic defects, due to heredity, exist, no very clear or satisfactory explanation is given of what initial physical and secondary psychic disturbances follow. A great deal has been written about increased or diminished tension of the cerebral arterial system, but to those familiar with the exciting causes or pathology of insanity the irregularity of cerebral hyperæmia or anæmia must be manifest. Why a periodical mania should develop, subside, and reappear, the environment and other influences being unchanged during the entire course, has not been definitely explained. Why a confusional insanity most unexpectedly follows a surgical operation when there is little or no shock, or a form of puerperal insanity appears weeks after parturition, and when the danger of local sepsis has long disappeared, suggests the necessity of some fresh explanation.

Before going further in this direction it may be well to say that my desire for more exact knowledge in regard to the pathology and ætiology of such everyday disorders as acute mania or melancholia was stimulated by the experience common to most of us, that, where psychic causes exist, not only the mental but the physical disturbance is usually entirely out of proportion to any cerebral shock or demand upon the brain, and it seems strange that where the most extreme kinds of mental strain exist in some individuals, they are attended by comparatively little or no general disturbance. I was led to reason that if subjects who are subjected to comparatively superficial mental strain rapidly develop great physical derangement, disturbances of assimilation, feebleness, and emaciation, and die in a few weeks, there must be something beneath all this—something that has been simply lighted up or induced by the preparatory condition into which, perhaps, hereditary influences entered to some extent, or not at all. The observations of Herter and Smith point to the fact that that protean neurosis, neurasthenia, is closely connected with some form of disturbed intestinal function, and Eccles and Gautier clearly recognized the insufficient activity in the oxidation processes with the presence of the products of incomplete metabolism, and with an increase of the combined sulphates in the urine. The excellent work of Bouchard, Rodriguez, Chardon, and Chevalier Lavaure, and the more recent papers in your own country of Macpherson, Eccles, St. John Bullen, and Turner, have led to the inquiry whether a large number of acute in-

## THE CONNECTION OF INTESTINAL AUTOTOXIS WITH CERTAIN COMMON FORMS OF INSANITY.\*

By ALLAN McLANE HAMILTON, M.D.,

ONE OF THE CONSULTING NEUROLOGISTS TO THE MANHATTAN STATE ASYLUM,  
NEW YORK;

CORRESPONDING FELLOW OF THE MEDICAL SOCIETY OF LONDON, ETC.

UNTIL quite recently the therapeutics of mental diseases have been very primitive, in view of the pathological advances that have been made in so many different directions, and do not appear to have been seriously influenced by the important researches that have marked the last decade, so far as deranged metabolism is concerned. Even to-day the management of insanity nearly everywhere consists chiefly in quelling excitement by narcotics, overcoming depression by stimulants and tonics, and affording rest, isolation, and protection.

I have for several years been impressed with the somatic origin of various psychoses, especially those which were first classified and defined by Krafft-Ebing as "acquired," and by others ascribed to certain epochs, and I have looked for some more direct and reasonable causes than those which are ordinarily alleged to exist, reaching the conclusion that in very many instances the existence of defective oxidation will explain the clinical features of numerous insanities which were formerly

\* Read before the Medical Society of London, May 11, 1896.

sanities are really not after all due to primal intestinal disorders, and if even the course of the chronic psychoses must not be more or less modified by the same agencies: and whether, this being true, we should not in the future direct our treatment more than we have in the past to the care of the digestive organs, placing less reliance on the use of the conventional narcotics, or other familiar modes of treatment.

With this end in view I made many months ago a series of investigations, the results of which have been based upon experiments with animals and clinical observations conducted in the hospitals and asylums with which I have been connected, and in my own practice and elsewhere. More than fifty cases of different kinds of insanity have been observed, which include examples of acute and chronic melancholia and mania, simple delusional insanities, primal and terminal dementias, paralytic dementia, periodic, puerperal, and traumatic insanities, and the alcoholic and drug psychoses. The variation of the urine and feces was noted, and all the cases were carefully watched. It would be impossible in a brief paper of this length to more than summarize my results, and it is my intention this evening to simply sketch the work that has been done.

The experiments were undertaken to determine first whether there was any specific or noso-toxicity of the urine of the insane; and, if so, what the nature of such toxicity was; next, to discover, if possible, how important and general was the theory of uric-acid poisoning; and again, whether mental disorders were produced and modified by an autotoxæmia; whether the offending substances were the leucomaines or the intrinsic products of putrescence in the intestines. According to Marie and Bosc, the urine of insane persons possesses a toxicity which varies and is more or less identified with the different forms of insanity. They found that it was increased in agitated melancholia, as well as in persecutory insanity and excitable mania, while there was only a normal amount in quiet mania, and the toxicity was much reduced in purely stuporose and senile conditions. As the result of their experiments upon animals, hyperthermy and anæsthesia, auditory hyperæsthesia, diminished reflexes, psychomotor disturbances, and agitation ensued; but their conclusions, however, were doubted by Seglas and Ballet, who contended that there was nothing distinctive in the findings. For the purpose of satisfying myself as to the possible extent of noso-toxis, I selected six patients, from whom the urine was obtained weekly, and conducted a series of experiments to determine whether there was any uniformity or peculiarity, but with negative results.

Rabbits were chosen and kept closely under observation for a number of days, and, although some of them manifested rather striking nervous symptoms, as well as the hyperthermy observed by the authors referred to, the results were neither constant nor characteristic. Two of the patients whose urine was injected were

melancholics, one was a case of acute mania, another of chronic mania, a fifth of parietic dementia, and the sixth of periodical insanity. The resulting effect seems to depend very much upon the increased specific gravity of the specimen, and on the evidences of intestinal disorders and malnutrition. The urine of the parietic was always exceedingly toxic, which property was possessed by that of the periodic patient, whose urine showed a large amount of indican, while in only one of the other cases of mania in which the specific gravity of the urine was high, was there any result effected by its injection. In these dense urines there was an increase of the combined sulphates and urea. Large quantities, amounting to forty cubic centimetres of the urine of the melancholic, were injected without any apparent effect, so I was forced to abandon the idea that the excreta, in certain forms of insanity, presented specific toxic qualities. The only interesting psychic manifestation besides an apparent stupidity was the causation, in the rabbit that had received the injection of urine from the parietic patient, of rather a curious condition, which led me to believe that hallucinations of vision existed. There was absolutely nothing, however, that could be regarded as uniform, although frequent injections were made. So far as the influence of uric poisoning is concerned, I am clearly of the opinion that it has not as much to do with the genesis of mental disease as is alleged for it by the more enthusiastic, but in those cases in which it is supposed to play an ætiological part it is a very grave question whether its presence is not indicative of another kind of poisoning, which is the result of the destructive metabolism of nuclein, the amount of uric acid measuring the amount of leucocyte activity, and we are confronted with the query whether the initial destruction is not due after all to a primary intestinal disorder. The symptoms produced by the injection of urea and uric acid into animals, as detailed by Bouchard, though possessing a certain uniformity, have too limited significance in view of the varying symptoms which enter into the clinical picture of various insanities due to the absorption of putrescent substances. One distinguished writer has announced that melancholia especially is due to the accumulation of the second of these substances, and that one of its important features is the increased arterial tension, an assumption which I do not think is always tenable, though it may occasionally exist, for my own experience teaches me that there are many cases of this mental disease where the arterial condition is the reverse. So far as the influence of retained leucomaines is concerned, there seems to be much more reason to believe that, in the subjects where there is the retention of the physiological products of waste, disorders of the nervous system generally ensue. Salomon has found that when paraxanthin was introduced into the blood stream of the smaller animals, states were induced resembling some of the psychoses observed in man, and I am informed that

he has produced in a mouse a condition, so far as objective appearances are concerned, closely resembling stuporous melancholia. His experiments in 1892, and those of Mendel subsequently, prove that it was possible to produce symptoms similar to those of katatonia by the injection of this substance into white mice, dogs, and cats. Vaughan injected a small quantity of hypoxanthin into a frog, which some hours afterward became convulsed. Remembering that paraxanthin and heteraxanthin are the organic analogues of the vegetable alkaloids caffeine and theobromine—one being a dimethylxanthine and the other a methylxanthine—the natural speculation may arise whether the effect upon the nervous system of the latter might not be duplicated in the organic extracts, although Vaughan and others have concluded that the organic alkaloids obtained from ptomaines, or rather diamines, have not the identical physiological effects of such vegetable alkaloids as atropine, morphine, coniine, etc.

At my request, Dr. E. E. Smith, of New York, prepared a quantity of hypoxanthin in the following manner:

Liebig's extract of beef was dissolved in a large volume of water, and lead acetate added till no further precipitate was produced; the solution was filtered, the filtrate treated with hydrogen sulphide till the lead was precipitated, and this filtrate evaporated to a small volume and the creatine crystallized in the cold. The evaporation of the crystals was aided by the subsequent addition of several volumes of an eighty-eight-per-cent. alcohol. The mother liquor, after removal of the alcohol, was precipitated with ammonia and silver nitrate, the precipitate dissolved in nitric acid of specific gravity 1.1 by the aid of heat, and the solution cooled, when crystals of hypoxanthin silver nitrate separated out. This salt was suspended in water, decomposed with hydrogen sulphide, and the filtrate evaporated to a small volume, whereupon hypoxanthine nitrate crystallized out.

Microscopical examination of the crystals of hypoxanthine nitrate showed the characteristic form with the exception only of one or two acicular crystals, doubtless mere traces of adenin.

With this product I conducted a series of experiments on rabbits and monkeys. Hypoxanthine was mixed with the food and given in doses varying from ten to fifteen centigrammes at intervals of an hour, until a hundred and fifty centigrammes were given, without any satisfactory results so far as the production of symptoms of any kind was concerned. Of four rabbits, only one presented toxic symptoms, and to a Java monkey as much as fifty centigrammes were given without any apparent effect. The susceptible subject was a lively nervous rabbit weighing three pounds and a half, to whom twenty centigrammes were given in bran. Within five minutes after taking it, the animal manifested some excitement, rubbed its paws vigorously, and

was restless and disturbed by noise or jarring of the floor; its ears became exceedingly congested and its reflexes were affected by the slightest tap. This irritability gradually subsided, so that at the end of two hours it became dull and stupid, and did not resist pinching or other forms of stimuli. Its paws could be pricked with impunity and without any apparent evidence of feeling. Its pupils were widely dilated, and the pupillary reflex was lost, while there seemed to be retinal insensibility, for it did not mind a lighted match or the application of an irritant. When with much urging it was made to move, it dragged its hind legs, and there was no effort to escape. It remained in a condition of torpor for over an hour and gradually resumed its normal condition of liveliness. The same rabbit subsequently manifested identical phenomena when twenty cubic centigrammes of a fifty-per-cent. solution were introduced into the circulation.

It would appear that the intestinal toxalbumins have more to do with the production of disturbance of the nervous system than the leucomaines, which undeniably have an effect, though not a very marked one. Selmi obtained ptomaines from the urine of a paretic patient which, when injected into an animal, produced convulsions, and according to Vaughan and others most of the ptomaines produce convulsions and other forms of hyperkinesia.

A study of the cases that have formed the basis of observation for the past year unquestionably bears out the assumption that disturbances of the gastro-intestinal tract, more often than is generally supposed, are attended by bacterial necrosis and the introduction into the general circulation of certain very virulent toxic agents whose effects are expended mainly upon the nervous system. I think I am safe in saying that nearly all the rapidly developing confusional insanities have this explanation, and we must, therefore, be on the alert for such a cause, even when the case has commonplace features. No other alternative has presented itself so strongly to my mind as that of intestinal putrefaction, and in all the patients whose urine was examined a decided increase in the amount of indican was found, even when the diet was carefully regulated.

A sudden and rapid development of incoherence, then, with malassimilation, highly colored urine, and delusions that are unsystematized, clearly suggests an inquiry into the condition of the organs of digestion, and the first step should consist in a complete examination of the urine and feces. Even in the chronic insanities the occurrence of *acids* and convulsions has, in my experience, been attended with some defect of metabolism, and the determination of the sulphate ratio has afforded me great help in diagnosis.

Turner, in an admirable paper, determined that the ratio of the preformed and aromatic sulphates in general paresis, while not very markedly increased in the early stages, became decidedly so in the established dis-

ease or coincidentally with the *accès*, the ratio rising and afterward subsiding.

It would appear, from my own cases, that those usually showing little or no excess of combined sulphates include examples of chronic delusional insanity, chronic melancholia, and some of dementia. In individuals whose mental condition was one where imperative concepts played the chief part, the urine showed nothing that was unusual, at least so far as absorption of intestinal putrefactive products was concerned.

From the data obtained from all available sources, my own cases and others, it would appear not only that the ratio of the sulphates between themselves and to the urea, and the presence of indican in considerable amount, are indications of intestinal putrefaction, which no doubt influence the course of various insanities, but that a large increase of the combined sulphates has much to do with the genesis of various psychoses, and Bence Jones has noted this in delirium, while Regis and Chevalier Lavaure recognize the gravity of septic poisoning in other well-known mental conditions, but so far, though our knowledge is somewhat crystallized, the matter is still unsettled, and there is much to be learned with regard to the importance of the sulphatic ratio. My investigations convince me that the presence of indican in the urine of the insane has the most significance, so far as constancy is concerned, for in nearly all the cases which were not simply evolutionary it has been discovered in excessive quantities, in connection with the development or as a feature of an exacerbation of an existing mental disorder.

What is an excessive quantity? may be asked. The reply is: Any amount that can be detected in the urine by Jaffe's test, even if a weak reaction is obtained. Smith fixes the harmful amount at anything more than five milligrammes in twenty-four hours, and the color may vary from a light pink to a deep purple. In two or three of my cases the appearance of indican was nearly always coincident with the outbreak of new symptoms or the intensification of old ones, and it always marked the existence of a putrefactive process, bearing out the axiom that the presence of indol indicates bacterial death in the intestines. As regards the special connection of urinary findings of this kind with different kinds of mental disease, it would appear that in all forms with loss of weight and depression the sulphate ratio between the combined and preformed sulphates was lower than in health. It has been pointed out by Senator that an abundant appearance of indican under these circumstances indicates starvation, and, from the lowered quantity of preformed sulphates found in cases of inanition, Herter and Smith agree with him. In melancholia especially, the amount of indican depends upon whether the disease is of the stuporous or agitated variety, the quantity of this substance found not being so great in the former. In one of the series of cases in Bloomingdale Asylum, examined by Dr. Dodd, it was

absent only once in a series of seventeen examinations, and always existed in large quantity with a corresponding decrease in the sulphate ratio, the latter varying from one half to one twelfth. In such cases of melancholia the blood-corpuscles and hæmoglobin seem to undergo a decided diminution, which has been observed in other conditions where anæmia existed in association with the increase of the combined sulphates and the presence of large quantities of indigo blue. I believe it was the late Sir Andrew Clarke who first pointed out the connection between anæmia and the absorption of the products of intestinal putrefaction. In all the melancholic and other patients in which the coincidence existed, the variations in the hæmoglobin and red corpuscles were closely connected with the absorption of toxic substances, the extent of which was announced by the increase of the combined sulphates, while the physical appearances were those of malnutrition. Such a case was that of a young lady whose feebleness and exhaustion were extreme, and were coincident with a mental condition manifested by an initial neurasthenia, with digestive disorders, depressing delusions, self-accusation, and attempted suicide. The hæmoglobin was reduced to thirty per cent., and the red corpuscles to less than three hundred thousand. This state existed in connection with a low sulphate ratio and a constant output of indican, notwithstanding the fact that appropriate diet was ordered. The course of treatment, in which nuclein-forming agents and lavage and intestinal washing figured, cured her in two weeks, after arsenic and iron and forced feeding had failed.

Some forms of melancholia are undoubtedly due to autotoxis dependent upon impaction and copremia, although the passage of an apparently sufficient amount of fecal matter may incline the observer to ignore the existence of constipation as a cause. If the urine of such patients is examined, a large excess of aromatic sulphates will be found, with increased indigo blue and possibly skatol. Two such cases have made a great impression upon me, for the reason that, notwithstanding the passage of what looked like fair-sized stools, which to all appearance contained the recognized *débris* of food taken within twenty-four hours, such was not the case, and a certain accumulation existed which gave rise to a melancholia of an almost stuporous kind at first, but which subsequently became excited after a week or two, and was quickly cured by the recognition of the obstruction and its removal. In this case the increase of ethereal sulphates was enormous, the presence of indican being detected in large quantities. After the bowels were emptied and naphthalin was given, the delusions, which were more or less systematized, quickly disappeared, and the urine became normal. It would seem that circumstances sometimes modify the course of a chronic melancholia by favoring the increased elimination of more or less toxic products, so that an im-

provement in the mental state is witnessed, at least for a time. In a case reported by Eccles, an attack of influenza in a melancholic caused an increase in the elimination of urea and the leucomaines, with a coincident improvement of the mental depression, which, however, reappeared when the pyrexia subsided.

(To be concluded.)

## THE

# SOURCE OF URIC ACID IN THE ORGANISM.

A REVIEW OF SOME RECENT PAPERS.

By ALBERT MATHEWS,

MARBURG UNIVERSITY, GERMANY.

ALTHOUGH in man and most mammalia uric acid normally constitutes but a small portion of the nitrogenous outgo, it may in many diseases—i. e., acute fevers, rheumatism, gout, leucocythæmia—be excreted in considerable amounts. The determination of the origin of this substance in the body has thus a pathological and practical as well as a physiological interest. In birds and reptiles, as has long been known, uric acid forms the greater part of the nitrogenous excretion.

The origin of this acid in mammals and birds has until recent years been disputed. By Zalesky,\* Bartels,† Ererichs,‡ and Fleischer# the kidneys were regarded as the seat of its manufacture. This was shown to be erroneous by Chrzonszczewski,|| who observed in geese with extirpated kidneys a deposition of uric acid in the tissues generally; by Salkowski,^ who showed that in kidney disease uric-acid excretion was not materially diminished; and by Abeles,^ who found that the living kidney was unable to synthesize uric acid.

Virchow, and also Ranke, regarded the spleen as the seat of uric-acid formation, because, in leucæmia, this organ enlarged coincidentally with the appearance of the acid in the urine.

Facts soon accumulated, however, pointing toward the liver as the place of origin of uric acid in birds. Meissner‡ demonstrated that the liver in mammals contained more urea and in birds more uric acid than any other organ. Finally, the decisive work of Minkowski† proved that in birds the liver plays a predominant rôle in the formation of uric acid.

This author found, in working upon geese, that if the liver was extirpated or ligatured out of the circulation, the amount of uric acid excreted greatly dimin-

ished. In one case it fell from 1.042 gr. excreted in twelve hours before extirpation to 0.045 gr. in twelve hours after extirpation. In no case, however, did the excretion of the acid completely cease. At the same time there appeared in the urine great quantities of lactic acid, never present in normal urine, and the proportion of ammonia excreted rose to nearly five times its former amount. Furthermore, after the extirpation of the liver, such substances as glycocholic acid, ammonia, amido acids, asparagin, and asparaginic acid, the injection of which into healthy birds was followed by a great increase in uric-acid excretion, no longer had such an influence, but these substances were either excreted unchanged, or appeared in the urine as ammonia. These facts led to the following conclusions: (1) That ammonia was one of the substances out of which the normal bird organism formed uric acid; (2) that the liver was essential to this formation; and (3) that there was a small residual portion of uric acid in birds, the origin of which remained unexplained, and was hardly to be attributed to the liver.

It could not, however, be concluded from these experiments that the mammalian uric acid had a similar origin. On the contrary, many facts indicated that the formation of urea in mammals corresponded in them to the uric-acid formation in birds, and that mammalian uric acid had a quite different origin.

This was in part shown by the fact that the injection of substances such as glycocholic acid, leucine, asparagin, asparaginic acid, amido acids, and ammonium carbonate (Schlugen and Nencki, von Knieriem,\* Schmiedeberg,† Salkowski,‡ Halleworden,^), which greatly increased uric-acid excretion in birds, produced in mammals no alteration whatever in the uric acid, but instead a great increase in urea outgo. Von Schroeder|| discovered further that, if blood containing glycocholic acid, ammonium carbonate, or amido-acids was allowed to flow through still living mammalian organs, the liver alone was able to form urea. Kidney and muscle lacked this power. No one of the organs experimented upon formed uric acid. He also observed that if the liver was cut out of the circulation the organism no longer converted ammonia into urea.

These observations were confirmed and extended by the work of Nencki, Pawlow, and Zalesky.^ These observers discovered that if a fistula was made between the portal vein and the inferior vena cava so that blood

from the intestine no longer passed through the liver, the animals died in some days or weeks, showing every symptom of ammonia poisoning. In such animals it was found that the secretion of urea almost ceased and that great quantities of ammonia appeared in the urine. The uric acid was increased, instead of diminishing as in birds, but this, as will presently be shown, was in all probability an indirect effect. It was discovered, too, that after the Eck fistula had been made, a diet containing meat, glycocholl, or ammonia gave rise in the animals to symptoms of ammonia poisoning and resulted at times fatally.

An examination of normal animals gave the interesting result that the blood coming from the intestine in the mesenteric vein contained about five times as much ammonia as that in the vena cava inferior and ten times as much as the carotid blood, and, furthermore, that the mucous membrane of the stomach was exceedingly rich in ammonia. The authors concluded that ammonia was formed by the stomach mucous membrane; that it was carried to the liver and there converted, in part at least, into urea; and that this function of the liver was of very great consequence to the organism.

From the experiments just quoted, it became clear that the substances producing uric acid in birds produced urea in mammals; that the seat of the synthesis in both cases was the liver; that ammonia was a normal forerunner of uric acid in birds and of urea in mammals, thus showing a parallelism between the urea formation in mammals and uric-acid formation in birds. The experiments also showed that in mammals uric acid was not formed by the liver, and hence that mammalian uric acid was not formed in the same manner as the greater part of that found in birds.

The source of the uric acid of mammalia and a small portion of that in birds remained still obscure. Light was to come from an unexpected quarter.

Uric acid, as will be seen by a glance at the following formulae, closely resembles the so-called nuclein bases, xanthin, hypoxanthin, guanin, and adenin, bodies which are also found in the urine in small quantities.

This close resemblance made it probable that all had the same origin in the body. So, when Kossel\* showed

that the xanthin bases were the products of the decomposition of the proteidlike bodies called nucleins, found in the cell nuclei, he at once suggested that uric acid had a similar source. All attempts, however, to derive uric acid from these bases or from nucleins, either outside of the body or by injection into the latter, were succeeded in demonstrating that uric acid is indeed, failures.\*

Horbaczewski† took the problem at this point and under certain conditions, the product of nuclein decomposition.

By first digesting spleen pulp with water at 40° to 60° C. until decay began (eight hours), by which process a great part of the nucleins passed into solution, precipitating the albuminous matter with lead acetate, and then treating the filtrate with well-aerated arterial blood or superoxide of hydrogen for some hours at 40° to 50° C., he obtained a considerable amount of uric acid (one gramme of spleen yielded 2.5 milligrammes of uric acid). If the filtrate, instead of being treated with blood, was boiled, it yielded xanthin bases instead of uric acid. This experiment showed that the xanthin bases and uric acid were derived from the same mother substance. This substance, if oxidized before its decomposition, as probably occurred in the organism, yielded uric acid; if unoxidized, it yielded no uric acid but xanthin bases instead.

To show that this substance was derived from the nuclei, Horbaczewski isolated these by pepsin digestion, and extracted the residue with ether and alcohol. The clean nuclei thus obtained, when treated with blood as already described, yielded uric acid. By similar treatment he obtained uric acid from the liver, brain, lungs, thymus gland, and skin, both of calves and men.

The facts just sketched led at once to the conclusion that the appearance of uric acid in the mammalian urine was due to a cellular decomposition. The cells most readily decomposing are the leucocytes, so that it was not improbable that the bulk of the uric acid was derived from them. Many facts bore this out. In nearly all cases of leucocytosis uric-acid excretion increases. This is the case in leucæmia (leucocythæmia) and the normal leucocytosis after eating meat. Horbaczewski found, in the examination of five men, that after a meal containing meat the number of leucocytes increased from fifty to sixty per cent., and uric acid excreted rose, in one case, two hundred and seventy per cent.; after a vegetable diet the leucocytes increased only from one to twenty-three per cent.; and the increase in uric acid excreted was only from two to ninety-four per cent. In these cases of carcinoma ventriculi there was no digestive leucocytosis, and in these cases there was no increase in uric acid.

\* See Stadthagen. Virchow's *Archiv*, vol. cix, p. 420. V. Mach. *Archiv f. exp. Path. u. Pharmac.*, Bd. xxiv, 1888.

† Sitzungsber. der Wiener Akad., Bd. c, 1892. *Monatshefte f. Chemie*, 1888.

The influence of drugs upon uric-acid excretion found here a possible explanation. Thus quinine, which diminished uric acid, diminished also the number of leucocytes; atropine had a similar effect; pilocarpine, on the other hand, caused a pronounced leucocytosis, accompanied by a rise in uric-acid excretion; antipyrine and antifebrin, which in small doses diminished uric-acid excretion and increased it in large, caused in small doses a slight increase in the number of leucocytes, due, perhaps, to their checking the process of leucocyte destruction.

The rise in uric-acid excretion after phosphorus poisoning, in acute fevers, in burns, and cachexia may also be due, Horbaczewski suggests, principally to the accompanying leucocytosis, although it may be due in part to the extensive destruction of other tissues occurring in these conditions.

Whether or not most of the uric acid in mammals is thus due to a decomposition of leucocytes has been the subject of keen research, which has, on the whole, confirmed Horbaczewski's position.

Jacob and Krüger,\* in a case of leucæmia treated with injections of spleen extract, observed a decided fall in the number of leucocytes after injection, and a decided and corresponding increase in the uric acid excreted. Richter † and Weintraud ‡ showed that in man ten grammes of the sodium salt of nucleic acid taken into the stomach, or the eating of substances rich in nucleins, as the thymus gland of the calf, produced a pronounced increase in uric-acid excretion. Hess § observed, after eating calves' thymus glands, an immediate increase in the nuclein bases in the urine. Jaksch || found that uric acid and the xanthin bases were never present in the normal blood, but only in dyspnoic states, pneumonia, nephritis, and anaemia. Weintraud ¶ found uric acid in the blood of men and dogs after feeding with nucleins. From the microscopical side, Gumprecht † observed in leucæmia a great degeneration of leucocytes. Kuhn ‡ carefully investigated the relations of leucocytosis to uric-acid excretion and came to the following conclusions:

1. In a number of diseases in which leucocytosis occurs, an increase in uric-acid excretion may be recognized.
2. The increase in uric-acid excretion can not alone be conditioned by the fever, since it occurs also in diseases without fever (cachexia leucocytosis).
3. The quick decrease of a leucocytosis coincides with a rise of uric-acid excretion.

4. Leucocytosis, experimentally caused, is coupled with an increase in uric-acid excretion; the latter reaches its highest point first when the leucocytosis disappears.

5. It is possible, also, without the medium of the leucocytosis, by introducing leucocyte-containing material (aseptic pus, thymus emulsion), to cause an increase in uric acid.

6. The injection of nucleins causes directly an increase in the excretion of urates. The coincident leucocytosis can not alone be answerable for the latter.

7. The leucocytes furnish a chief part, although not all, of the material out of which uric acid is formed.

The practical importance of Horbaczewski's discovery in the treatment of disease in which a large excretion of uric acid occurs is, of course, very great, but the papers which have thus far appeared do not yet permit of definite conclusions.

Kalisch \* gives the following summary, or diagnostic scheme:

I. Increase of alloxin bodies (uric acid and xanthin bases) *in toto*.

1. With leucocytosis (leucæmia).
2. Without leucocytosis (uretic diathesis).

II. Normal total amount of alloxin bodies, but bases increased and uric acid decreased.

1. Blood consumption.
2. Nephritis.

The experiments clearly indicate the great importance of diet in such conditions. Uric acid is increased by a diet containing nucleins and by pilocarpine, and decreased by a vegetable diet, by atropine and quinine, and acetanilide and antipyrine in small doses.

The work of Horbaczewski, together with that of Minkowski, Pawlow, and others, permits the conclusion that in birds the greater part of the uric acid, and in mammals the formation of urea, is brought about by a synthesis of ammonia with unknown bodies, in which the liver plays a predominant rôle; but that the uric acid found in mammals, and possibly a small part of the uric acid of birds, is derived from nucleins on the decomposition of cell nuclei, and chiefly from the nuclei of the white blood-cells.

#### NOTE OF

#### A CASE OF FACIAL HEMIATROPHY.

By ALBERT ABRAMS, A. M., M. D.,

PROFESSOR OF PATHOLOGY, COOPER MEDICAL COLLEGE, SAN FRANCISCO

THE following case, seen in consultation with Dr. S. Trask of this city, presents an unusual phenomenon. The case is interesting for two reasons: as a contribution to the limited number of cases of facial hemiatrophy and as emphasizing the close relation between the trigeminal and this disease.

\* *Deutsch. med. Woch.*, 1894, p. 644.

† *Ztsch. f. klin. Med.*, 27.

‡ *Berl. klin. Wochenschr.*, 95, No. 19.

§ *Vierteljahr. Cong. f. inn. Med.*, Wiesbaden.

|| *Ueber die klin. Bedeutung von Harnsäure u. Xanthinbasen im Blut.*

Berlin, Fischer, 1891.

¶ *Vierteljahr. Cong. f. inn. Med.*

‡ *Ibid.*

‡ *Ztschr. f. klin. Med.*, 95.

\* *Wiener klin. Wochenschr.*, 95.

The case is succinctly as follows: A. T., aged twenty-one years, bookkeeper; no neuropathic history; no history of alcoholism or syphilis. About a year ago he first noticed a feeling of tension in the skin over the left malar bone together with stoppage of the left nostril. Suffers from paroxysms of supraorbital neuralgia on the left side. It is for the latter affection that he has sought counsel. On examination, the mucosa of the left nostril is congested and shows occlusion beginning at the anterior tip of the lower turbinated bone. The septum is slightly deviated toward the left side. On the cartilaginous septum, just within the vestibule, is a slight erosion. A posterior rhinoscopic examination shows an abundance of lymphoid tissue. Sight and hearing are unaffected. On and below the left malar bone is a pigmented spot, of about the size of a dollar, which is depressed. The skin on this side of the face is atrophied and there is a decided absence of panniculus. The skin to a very limited extent over the malar bone is adherent to the subcutaneous tissues. The other structures on the left side of the face are in no wise affected. The electric reactions are quantitatively but not qualitatively altered. Examination of the cranial nerves, with the exception of the trigeminus, shows nothing abnormal. There is complete anæsthesia with analgesia of the skin supplied by the second branch of the left trigeminus. The left supraorbital nerve is painful on pressure. Smell on the left side is perceptibly diminished, although this anomaly may be quite independent of any trigeminal lesion. The sense of taste is unaffected. The masticatory muscles are not implicated. As in the average case of hemiatrophy, the left side of the face is implicated. The etiology of the affection in my patient is obscure. As in a few of the cases thus far reported, supraorbital neuralgia preceded the atrophy.

My case is especially characterized by pronounced alteration in the cutaneous sensibility in the affected region. This is an exceptional phenomenon in unilateral facial atrophy. The prevailing theories in explanation of facial hemiatrophy are: 1, that it is provoked by some lesion of the vasomotor system; and 2, that it depends on some disorder in the trophic fibres of the trigeminus. The latter theory is more in accord with prevailing opinion. Ruhemann\* demonstrated the close relation between facial atrophy and the trifacial. The case of Mendel,† which was likewise examined by Virchow,‡ is of considerable interest in explaining the pathology of this rare affection. His patient had died of phthisis. In the descending root of the trigeminus atrophic changes were demonstrated, a fact which would seem to indicate the presence of trophic fibres. As far back as 1839, Magendie\* demonstrated in dogs trophic disturbances resulting from division of the trigeminus.

These disturbances essentially duplicated all the phenomena of facial hemiatrophy. Many cases of the latter affection are best explained by regarding them as cases of peripheral neuritis, the resulting disturbances

depending on whether the trophic, sensory, or motor fibres of the trigeminus are affected. At the present time the preponderance of evidence is in favor of the hypothesis that facial hemiatrophy is a trophoneurosis.

## A RARE CASE OF TINEA VERSICOLOR.

By E. D. SMITH, Ph. C., M. D.,  
CHICAGO.

In *Morrow's System of Genito-urinary Diseases, Syphilology, and Dermatology* there occurs this statement in regard to tinea versicolor: "The disease has never been observed on the inner surfaces of the hands or the plantar surfaces of the feet."

In July, 1895, Mr. A. consulted me for trouble with his feet that gave him great uneasiness. The patient was a drinking man and feared this was one of the causes of the disease. He said it had been in existence for three years. When he came to me, he reported that he had consulted several physicians and none of them could tell him the nature of his disease.

On examination I found a patch on either foot. The rest of the body was free from the disease. Both patches were of considerable extent—on the left foot, covering that part of its under surface corresponding to the metatarsal bones; on the right foot, covering that part corresponding to the tarsal bones. On both feet there were several slight prolongations on to the sides of the feet. The patches were of a pale-red color, their peripheries being darker than their centres, which were nearly of the appearance of normal skin. The patches were easily distinguished by daylight, but with difficulty by lamplight. The microscope revealed the characteristic fungus.

He complained of slight itching, which was aggravated when his feet became warm as a result of exercise or from being in a warm room. The itching annoyed him most when, after going to bed, his feet became warm.

I began treatment by having him soak his feet in warm water, using plenty of soap to remove the thick, effete epidermis. Then I had him make applications twice daily (mornings and evenings) of a watery solution containing two drachms to the ounce of hyposulphite of sodium. To relieve the itching I gave him the following prescription—viz.:

R. Menthol.....	3 iiij;
Camphor.....	3 iiij;
Albolene.....	3 ij

M. et sig.: Apply locally every two hours.

The hyposulphite of sodium did not seem to effect a cure, and I directed that he use in its place the U. S. P. tincture of iodine. This was applied lightly, with a camel's-hair brush, once a day. A few applications of this effected a cure.

305 DIVISION STREET.

**The Buffalo Academy of Medicine.**—At the last regular meeting of the Section in Obstetrics and Gynecology, on Tuesday evening, the 27th inst., the following papers were to be read: The *Ætiology, Pathology, and Diagnosis of Mammary Inflammations*, by Dr. W. G. Taylor, and the *Treatment of Mammary Inflammations*, by Dr. Eugene Smith.

\* *Deutsche med. Wochenschrift*, 1889, 3, 55.

† *Deutsche med. Ztg.*, 1888, 33.

# CLASSIFICATION AND NOMENCLATURE OF DISEASE, PARTICULARLY IN SPECIAL BRANCHES.

By J. H. FARBER, M.D.,  
DAYTON, OHIO.

A PERFECT classification and nomenclature of diseases is none the less desirable in general practice; but in special work, owing to the wide fields that have been opened up in recent years, it is imperatively demanded.

In text-books of nasal diseases there is still much imperfection and confusion of classification. The individual worker must classify affections in such manner as seems best suited to his experience, and in writing upon cases he often finds it necessary to go over his Gray both in the article and in his own mind. There should be, however, no necessity for a word picture of differentiation of classification in each article. A correct classification, founded upon anatomy, pathology, and symptomatology, would obviate such necessity and aid research, statistics, and even diagnosis.

With this rather long preamble, I would respectfully submit the following classification and nomenclature of diseases of the nasal and contiguous sinuses. Without claiming for it originality and absolute perfection, it seems to me better than some of the old ones. It is a modification and an extension of that of Dr. Ingals, of Chicago.

Starting with rhinitis, we would have the following—diagrammatically:

Rhinitis.	{	Acute catarrhal.	{ Acute suppurative.
		Chronic catarrhal.	{ Chronic " "
Rhinitis. Chronic catarrhal com- plications.	{	Intumescent.	{ Simple.
		Hypertrophic.	{ Complicated.
		Atrophic.	{ All complications with
		Syphilitic.	{ various accessory
		Tubercular.	{ sinus disease.
Accessory sinuses.	{	Strumous.	
		Anteal.	{ Acute suppurative.
			{ Chronic " "
	{	Ethmoidal.	{ Anterior.
			{ Acute suppurative.
			{ Chronic " "
			{ Acute " "
			{ Chronic " "
	{	Frontal.	{ Acute catarrhal.
			{ " " suppurative.
	{		{ Chronic " "
		Sphenoidal.	{ Acute " "
			{ Chronic " "

Various local manifestations of specifically named diseases, such as lupus, rodent ulcer, etc., various growths in different locations, all modify conditions present, but do not of necessity require classification under separate forms.

In this classification I have eliminated ozæna. Where shall we put it? Its horrible stench declares its existence. In answer, it is commonly conceded to belong to one of two classes—syphilitic (hereditary or acquired) or strumous rhinitis.

In defense of the classification of chronic catarrhal rhinitis, I urge that all specialists will agree that cases they have seen seem to belong exclusively to one or the

other of the above forms, and that many cases will show two or three or more of the same forms at the same time, and frequently two forms in the same individual at the same time and even on the same side. Probably as good a defense as is needed for those who claim atrophy as a result of hypertrophy is the familiar fact of their coexistence. But there is no student of atrophy who will say that it is necessarily associated with ozæna. Therefore, we must dissociate them at once. But we may say that in ozæna there is atrophy. I am inclined to believe that ozæna occurs *only* in syphilitic cases. It will be impossible in many cases to elicit such history. I have seen many so-called strumous patients, subjects of catarrh, without any ozæna.

In speaking of ozæna, I mean those specific cases with the terrible odor, the large, crusty scabs, and the atrophic condition underlying; and *not* all cases with a bad odor. It is for this reason alone, if for no other, that the term ozæna should be eliminated. We shall eventually know why some cases of nasal disease are accompanied by the vile odor, if the syphilitic term is found unsatisfactory or untrue.

One of the best articles on ozæna is to be found in Burnett's *Ear, Nose, and Throat*, by Dr. J. N. Mackenzie, of Baltimore. But, unfortunately, he was compelled to stop just short of its true cause, and it still remains to be ascertained, but it can not now long deceive us. I regret that I can not offer more than the opinion that it belongs to the syphilitic form, and pathologically should show diseased bone in some of the cellular bones of the nose. I only hesitatingly advance this, but hope that it may be confirmed sufficiently often to establish its class.

It was not the purpose of this article to do more than attempt to classify the diseases of the nose, and we will leave further discussion of individual cases for a future paper. Too much emphasis can not be placed upon the advantage of universal classification, simple, comprehensive, and radical. Classification show ozæna alone without a definite class, and it is hoped we shall clear up its anatomy and pathology at once, thus bringing up a perfect classification.

32 WEST FIFTH STREET.

## Therapeutical Notes.

**Vaginal Suppositories.**—The *Journal de médecine de Paris* for September 27th gives the following formula:

R Acetanilide.....	7.5 grains:
Tannin.....	8 "
Extract of hyoscyamus.....	4 "
Sugar of milk.....	150 "

M. This is for one suppository, to be used for vaginal inflammation.

**Snuffs for Coryza.**—Lermoyez (*Traité de thérapeutique des maladies des fosses nasales*; *Therapeutische*

*Wochenschrift*, August 30, 1896) recommends the following prescription:

R Cocaine hydrochloride.....	7½ grains;
Menthol.....	4½ "
Salol.....	75 "
Boric acid.....	300 "

M. A pinch is to be taken every hour. It gives rise to an abundant flow of mucus, which is followed by relief. The following is the formula of a somewhat less irritating snuff:

R Cocaine hydrochloride.....	7½ grains;
Menthol.....	3¼ "
Bismuth salicylate, { each.....	75 "
Sugar of milk, }	

M.

**Belladonna in the Treatment of Cough.**—*Lyon médical* quotes the following formula from the *Bulletin médical de l'Algérie*:

R Infusion (1-to-400) of belladonna leaves.....	300 grains;
Antipyrine.....	15 "
Syrup of currants.....	1 ounce.

M. A teaspoonful may be given every hour to a child five years old, in whooping-cough and other paroxysmal coughs.

**The Treatment of Alopecia Areata.**—Brocq (cited in the *Wiener medizinische Blätter* for August 27) recommends the following prescription:

R Resorcin.....	3 grains;
Quinine hydrochloride.....	6 "
Vaseline.....	1 ounce.

M. This ointment is to be applied to the bald spots, but only a limited part of the surface is to be treated at one time. If the loss of hair continues, twenty drops of tincture of cantharides may be added to the ointment, or sulphur may be employed according to the following formula:

R Resorcin.....	6 grains;
Quinine hydrochloride.....	12 "
Precipitated sulphur.....	1 drachm;
Vaseline.....	1 ounce.

M. If this proves too irritating, a simple two-per-cent. ointment of boric acid may be applied after its removal. If the loss of hair is associated with seborrhœal eczema, it is often well to use mercurial ointment.

**A Vaginal Injection for Leucorrhœa.**—Lirola (*Revue internationale de médecine et de chirurgie*, September 10, 1896) recommends the following formula:

R Tannin.....	6 parts;
Alcohol, { each.....	3 "
Cresote, }	
Water.....	24 "

M. A tablespoonful is to be added to a quart of warm water, which may be injected as often as three times a day.

**A New Treatment of Cholera.**—M. Chauvin, of Liège (*Médecine moderne*, September 5, 1896; *Lyon médical*, September 27, 1896), appears to be an optimist. He thinks cholera ought to yield to this prescription:

R Dilute hydrochloric acid.....	15 grains;
German white pepsin, { each.....	23 "
Wine of opium, }	
Peppermint water.....	1,800 "
Syrup of orange peel.....	750 "

M. A "spoonful" (whether a teaspoonful or a tablespoonful is not stated) is to be given hourly until the alarming symptoms subside, then four times a day until recovery is complete.

THE

## NEW YORK MEDICAL JOURNAL,

*A Weekly Review of Medicine.*

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 31, 1896.

### THE MEXICO MEETING OF THE PAN-AMERICAN MEDICAL CONGRESS.

We have no doubt that the meeting which is to be held next month in the City of Mexico will be well attended, well conducted, and productive of much good. But it is earnestly to be wished that all these features may be manifest in a superlative degree. To that end, we hope that all American countries will be well represented, and it is especially incumbent on the physicians of our own country, we think, to be present in large numbers, for the reason, if for no other, that our Mexican brethren entered heartily and most effectively into the work of the meeting that was held in Washington three years ago. The idea of holding such congresses was conceived and first promoted in the United States, and it was certainly a graceful act for so many physicians from other American countries to fall in with the project; it would be almost rude on our part if we failed to reciprocate now to the best of our power. True, the times are hard and the trip is necessarily expensive, but there are many who can afford it, and certainly the transportation companies, both maritime and overland, appear to be taking great pains to make the journey agreeable and of reasonable expense.

But it is not by any means solely to discharge an obligation that we urge our readers to go to Mexico. They will undoubtedly find great pleasure and profit in the undertaking. The natural beauty of Mexico and its agreeable climate at this season of the year need no proclaiming, but beyond all that there is the certainty of there being much for us to learn from our neighbors. It will be very interesting, we fancy, to see how they provide for the comfort of patients under their climatic conditions, and we are much mistaken if they do not exert themselves to make their visitors practically acquainted with the great array of medicinal plants indigenous to their country and virtually confined to it. Concerning many of those plants we have but hazy and confused ideas derived from the tales of travelers, often contradictory, inconsistent, and to a great extent legendary. There may be an opportunity at the meeting to see many of these plants that we have only read of, perhaps to see some of them living. We should then surely add materially to our certain knowledge of the

materia medica and enlarge the field of our necessities. We do not wish to convey the idea, or favor its being entertained, that it is only with regard to matters peculiar to their own country that the Mexicans can add to our knowledge; they are a clever people and by no means content with studying and mastering problems affecting themselves alone. Medicine as it is cultivated in all other civilized countries, in all its branches and with all nicety and precision, is cultivated in Mexico also, by men of learning, quickness of apprehension, and soundness of judgment. We may be sure that there is much to be gained on all sides in the company of such men—a due giving and receiving, reciprocal benefit. Let nobody among us set down attendance at the meeting as a pleasure trip and nothing more; it will be that and very much more.

#### THE BILHARZIA HÆMATOBIA AS A CAUSE OF URETHRAL FISTULÆ.

Two physicians practising in Alexandria, Egypt, Dr. Trekaki and Dr. von Eichstorff, have made what is probably the first serious study of the connection between urethral fistulæ and the trematode known as the *Bilharzia hæmatobia*. They publish their account in the September number of the *Annales des organes génito-urinaires*. It contains condensed histories of seven cases of fistula due chiefly if not entirely to the parasite. In none of them was there any stricture or other obstacle to explain the production of the fistula; neither the antecedents of the patients nor the most minute urethral examinations cast any doubt on this statement. There were, however, certain periurethral encroachments on the lumen of the canal, which readily yielded before a large sound, and the authors say that the suppurating and bursting of these lesions, due to the irruption of the parasite's ova outside of the natural urinary passages, are occurrences indispensable to the development of the fistulæ.

It seems that the formation of these fistulæ is not uncommon among persons infested with the worm; during the years 1894 and 1895 a hundred and nine patients affected with the parasite were treated in the Deaconesses' hospital, of whom forty-three, or forty per cent., had urinary fistula. Most of the fistulous patients are inhabitants of the Delta of the Nile. The fistulæ are of three kinds—urethro-perineal, urethro-scrotal, and urethro-penile. These fistulæ have not thus far been observed in Europeans residing in regions where the parasite abounds, and, indeed, they are rarely affected by it.

In the surgical treatment of these fistulæ there

are two cardinal points—to clear away the indurated tissue completely and to divert the stream of urine, as practised by Mackie and Varenhorst. The patient having been anesthetized and placed in the lithotomy posture, a large grooved sound is introduced into the urethra. Then the perinæum is incised and all indurated tissue cut away. When the operator has made sure of this, he performs perineal urethrotomy. A large drainage-tube is then inserted and the perineal wound is packed with iodoform gauze. This is the procedure generally adopted and the one that best fulfills the ætiological indications.

The authors sum up as follows: 1. Among the different causes that give rise to urethral fistulæ, the *Bilharzia hæmatobia* should always be taken into account. 2. These fistulæ originate in lesions produced by the irruption of the ova of the parasite into the periurethral tissues and the formation around the ova of changes which, under certain definite conditions, give rise to one or more fistulous tracts. 3. These fistulæ are in all respects like urethral fistulæ due to gonorrhœa or other causes, and are never preceded by urethral stricture. 4. They are endemic in Egypt and are observed in forty per cent. of the fellahs affected with tropical hæmaturia caused by the *Bilharzia hæmatobia*.

#### MINOR PARAGRAPHS.

##### A CHANGE OF NAME.

THE editors of *Mathews's Medical Quarterly* announce that with the January issue of that publication its name will be changed to *Mathews's Quarterly Journal of Rectal and Gastro-intestinal Diseases*. This is a change which has been deemed necessary for some time, as it is essential that the title of a medical journal should convey to the reader an idea of its contents, and this has not been the case with its name from the beginning. There will be no change in the policy of the journal in the least. As it continues to be the only English publication devoted to the diseases and surgery of the rectum and gastro-intestinal tract, the articles which will appear in it will be limited to these subjects. The journal will continue to be edited by Dr. J. M. Mathews and Dr. Henry E. Tuley and published in Louisville.

##### THE PHOTOGRAPHER AND THE IMPENDING ATTACK OF MEASLES.

THE *Sun* lately copied from the *Rochester Democrat and Chronicle* a tale said to be vouched for by a well-known clergyman who "always has a fund of amusing yarns at his tongue's end." The story, in brief, is that a handsome woman sat for her picture to a photographer of great skill and reputation, and that, to his utter confusion and the lady's great disappointment, he could not get a tolerable likeness, although he made three attempts. The next day he got a note from the lady in which she said: "Were you to see my face to-day,

it is possible your failure of yesterday might be logically explained. It is a perfect mass of eruptions from the measles which made their appearance during the night . . . Is it possible the condition of my skin was such that the sensitive plate reproduced it?" The story goes on: "It was even as she suggested. That which was so near the surface, but had not yet penetrated the skin, was clearly brought out by the photography. In other words, the measles were [*sic*] photographed before they [*sic*] appeared." So, measly pimples form somewhere in the depths of the body and go to the surface like bubbles! How beautifully this conception would once have been held to bear out the humoral pathology!

## ITEMS.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 27, 1896 :

DISEASES.	Week ending Oct. 20.		Week ending Oct. 27.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	37	12	26	7
Scarlet fever.....	63	2	80	5
Cerebro-spinal meningitis.....	4	4	0	0
Measles.....	36	2	61	2
Diphtheria.....	142	17	175	21
Tuberculosis.....	137	110	174	101

**The Second Pan-American Medical Congress.**—Dr. H. L. E. Johnson, chairman of the transportation committee, announces the following transportation rates to the delegates and their families and friends for the meeting to be held in the City of Mexico, Mexico, on November 16th to 19th inclusive:

The New England roads have made no reduction at all in rates, and the trunk lines have made no general reduction, but have agreed to special rates from the points mentioned in their territory, viz.: From New York city to the City of Mexico and return, \$78.50; from Philadelphia and return, \$76.00; from Baltimore and return, \$73.50; from Washington and return, \$71.50. Those attending the congress from the New England States and the territory of the trunk lines east of Pittsburgh, Erie, and Buffalo, will purchase regular local tickets to the nearest point mentioned in the reductions, either New York city, Philadelphia, Baltimore, or Washington, and at either of these cities purchase the through ticket at the reduced rates to Mexico and return as above stated. Should the delegates desire to enter Mexico by one gateway, say Eagle Pass, and return via another gateway, either Laredo or El Paso, an additional charge of \$5.75 total will secure such privilege. Pullman berths from New York, Philadelphia, Baltimore, or Washington to the City of Mexico will cost \$23 each way on regular trains over any line. Delegates residing in the central traffic territory, embracing the territory from Buffalo, Pittsburgh, and Parkersburg, W. Va., in the East, to Chicago and St. Louis in the West, will be accorded a round-trip ticket to the City of Mexico over any of the lines on the payment of one first-class fare. Delegates residing in the western traffic territory will be accorded the round-trip ticket to the City of Mexico for one fare over the following roads only: Missouri Pacific, Illinois Central, Wabash, Chicago and Alton, Atchison, Topeka, and Santa Fé, Chicago, Rock Island, and Pacific, Chicago, Great Western, and Burlington, and Cedar Rapids and Northern. Delegates residing in the southern Pacific territory will be accorded the one-fare rate to the City of Mexico and return. The three Mexican lines have accorded the round trip for one first-class fare.

*The Ocean Route.*—The fare over the Ward Line for the round-trip from New York city to the City of Mexico, via Tampico, has been reduced, and for this occasion will be \$78, including meals and stateroom. The fare one

way, going or returning, including meals and berth, will be \$2. The trip either way is made in ten days. Steamer will leave New York city on November 4th; tickets good until December 31, 1896. Those desiring to go by boat and return by rail, via El Paso, will pay \$11.75. The expenses for sleeping car for one night and meals between Tampico and the City of Mexico will amount to about \$4 in American money. Returning, the sleeping car rate for a berth is \$9 Mexican silver, or \$4.50 American money, between the City of Mexico and El Paso, and \$15 American money from El Paso to New York, or arrangements may be made to return by the special train.

*Individual Trips.*—Individual trips over the B. & O., or any of the roads from Washington, D. C., to the City of Mexico and return will cost: Fare, \$71.50; Pullman berths there and return, \$46; meals both ways, \$30—total, \$147.50. \$5.75 extra through one gateway, say Eagle Pass, and returning via either Laredo or El Paso. This route is made in about six days and will require a change of cars at St. Louis, Mo., and San Antonio, Texas. The rate from New York city will be the Washington rate, plus \$7. The Philadelphia rate will be the Washington rate, plus \$4.50. The Baltimore rate will be the Washington rate, plus \$2. The Pullman charges will be the same, \$46 going and returning from these cities. Intermediate points in proportion, both fare and Pullman.

Tickets from New York and Washington over the trunk lines will be sold from November 5th to 8th, inclusive, only, at the rates mentioned above.

**The Official Train.**—Special service is arranged for with the American Tourist Association, of Chicago, under the escort of Mr. Reau Campbell, general manager, who will provide a special train of sleeping and dining cars to run through from Chicago, Cincinnati, and St. Louis to the City of Mexico and return, connecting with the B. & O. R. R. trains from points east and north. This will be the official train and route, and will run on the following special schedule:

Leave Chicago.....	Ill. Cent. R. R.	Tuesday, Nov. 10, 9 A. M.
Leave Cincinnati.....	B. & O. S. W. Ry.	Wednesday, " 10, 9 A. M.
Leave St. Louis.....	Iron Mtn. Route	Tuesday, " 10, 8 P. M.
Arrive Little Rock.....	" "	Wednesday, " 11, 8 A. M.
Leave Texarkana.....	T. & P. Ry.	Wednesday, " 11, 1 P. M.
Arrive San Antonio.....	I. & G. N. R. Ry.	Thursday, " 12, 6 A. M.
Leave San Antonio.....	S. Pac.	Thursday, " 12, 11 A. M.
Leave Eagle Pass.....	Mex. Int. R. R.	Thursday, " 12, 5 P. M.
Leave Torreon.....	Mex. Cent.	Friday, " 13, 7 A. M.
Arrive at Zacatecas.....	" "	Friday, " 13, 7 P. M.
Leave Zacatecas.....	" "	Saturday, " 14, 11 A. M.
Arrive at Aguas Calientes.....	" "	Saturday, " 14, 1 P. M.
Arrive at Silao.....	" "	Saturday, " 14, 6 P. M.
Arrive at Irapuato.....	" "	Saturday, " 14, 7 P. M.
Arrive at Querétaro.....	" "	Saturday, " 14, 10 P. M.
Arrive at City of Mexico.....	" "	Sunday, " 15, 7 A. M.

The only stops going down will be at San Antonio, Texas (where passengers from New Orleans and the South may join the special train), and at Zacatecas, Mexico. On the return stops will be made at Querétaro, Aguas Calientes, San Luis Potosí, Tampico, and Monterey, with side trips to Guadalajara and Guanajuato, if the party so desire.

The official train will start on the return trip after the close of the congress in ample time to make these stops and reach Chicago, Cincinnati, and St. Louis on December 1st, the time of the tour being twenty-one days. The itinerary will be published in the City of Mexico. The train is scheduled to go and return via St. Louis and the Iron Mountain Route. Arrangements will be made for those desiring to return via the Southern Pacific and New Orleans and Illinois Central Railroad, if notification is made before starting, and tickets are secured accordingly. The rates for the official train are as follows:

From Chicago to the City of Mexico and return.....	\$190.10
From Cincinnati " " " " " .....	189.05
From St. Louis " " " " " .....	183.55

These rates include railway and sleeping-car fares; meals in dining car; meals at hotel in the City of Mexico; special street cars at stopping places; steamer on the Panuco River from Tampico, and every necessary expense of the trip of twenty-one days; if extended, the charge will be \$4.75 a day.

for each person. A train of palace sleeping and dining cars is being specially prepared. Supplies for dining cars will be taken from Chicago. The cuisine is placed in competent hands. Waulesha water served at all meals, and wine at dinner. A double berth is assigned to each person. Man and wife have the entire section. Berths and sections reserved for the complete tour. Railroad tickets should read according to the itinerary given above and for the following roads in Mexico:

Mexican International Railway..... Eagle Pass to Torreon.  
Mexican Central Railway..... Torreon to the City of Mexico.  
Mexican Central Railway..... the City of Mexico to Tampico.  
Monterrey and Mexican Gulf Railway..... Tampico to Tuxtepec.  
Mexican International Railway..... Tuxtepec to Eagle Pass.

A rate of one fare will be made from all important points plus \$5.75 for the return via Tampico. Payment for special train accommodations may be made on the train at Chicago, Cincinnati, or St. Louis, the amount of which is \$122, when the passenger presents his round-trip railroad ticket or passage to City of Mexico. Berths and sections may be reserved by addressing Reau Campbell, General Manager, American Tourist Association, 925 Old Colony Building, Chicago, inclosing check for \$30, which will be deducted from the final payment made on the train, or returned if, for any unforeseen reason, the party can not go. Or the total amount may be remitted to Mr. Campbell, if desired, and will be returned if trip is not taken. It is advised that reservations should be made at the earliest possible moment in order that a sufficient number of sleeping and dining cars may be provided, as under no circumstances will more than two persons be assigned to a section, thus assuring perfect comfort to all. Delegates taking the special train will purchase railroad tickets from their place of residence to the City of Mexico and return at the rate of one fare, and purchase sleeping car tickets to the nearest starting point of the special train, either Chicago, Cincinnati, or St. Louis. The special train starts as scheduled, and ample time should be allowed for making connections from local or connecting trains.

Mr. Campbell will furnish the fullest information in detail, send maps, guide-books, etc., if application is made to him at 925 Old Colony Building, Chicago; also send name and address to Dr. H. L. E. Johnson, Chairman Transportation Committee, 1402 L Street, Washington, D. C., in order that he may make up an official list of the delegates and their party attending the congress from the United States. Delegates may either live on the train and take their meals in the dining car while in the City of Mexico, or secure rooms at the hotels for from \$1.50 to \$5 a day, Mexican money. Meals on the train or in the hotels are included in the price of the ticket; there are no extras whatsoever, except rooms at hotels. Before reaching the City of Mexico, the delegates should decide whether they will want rooms at hotels or will remain in the cars, that arrangements may be made ahead and rooms reserved.

**The "Official" Train to Mexico.**—Dr. Charles A. L. Reed, of Cincinnati, has been thoughtful enough to issue a circular of information in which he says that, inasmuch as the rate to the City of Mexico on the occasion of the meeting of the Pan-American Medical Congress is open to the public, a very large number of people are expected to avail themselves of it. A number of excursions on the popular plan will no doubt be arranged, some of them by persons unfamiliar with the business, and will in all probability be patronized to the point of discomfort. It was in anticipation of this that the regular committee on transportation arranged with Mr. Reau Campbell, of the American Tourist's Association, for a handsomely equipped "official" train of Pullman cars to be personally conducted by himself for the exclusive use of delegates, their families, and their friends. *This is the only "official" train, and it will leave Cincinnati on Tuesday, November 10th, at 9 A. M.* Physicians are asked to bear this in mind, that they may not be misled by representatives of mere excursion enterprises, and thus be deprived of the opportunity of traveling with their friends.

**The New York Quarantine Service.**—Among the many improvements instituted by the present health officer, Dr. Alvah H. Doty, for the rigid carrying out of quarantine

regulations, the fitting up and equipment of the steamer James W. Wadsworth is not the least in importance. The steamer has recently been supplied with the necessary apparatus for the disinfection of passengers, clothing, ships, and cargoes by steam, formaldehyde, and bichloride-of-mercury solution, and will without doubt prove an invaluable aid in arresting contagious diseases at our port entrance.

**The American Laryngological, Rhinological, and Otolological Society.**—Dr. W. Scheppgrell, the chairman of the Southern Section of the society, announces that a meeting of this section will be held in New Orleans on the 3d and 4th of March, 1897. This date has been selected in order to enable visiting members to see New Orleans during the carnival season, and to secure half-rate railroad transportation.

**The New York Obstetrical Society.**—At the annual meeting, held on October 20th, officers for the ensuing year were elected as follows: President, Dr. Robert A. Murray; vice-presidents, Dr. C. A. von Ramdohr and Dr. George W. Jarman; recording secretary, Dr. Arthur M. Jacobus; assistant recording secretary, Dr. Le Roy Brown; corresponding secretary, Dr. H. J. Boldt; treasurer, Dr. J. Lee Morrill; pathologist, Dr. G. C. Freeborn.

**St. Luke's Hospital, South Bethlehem, Pennsylvania.**—"Hospital day" was celebrated on Saturday, the 17th inst. Dr. Henry Dwight Chapin, of New York, delivered an address, and a class of nurses was graduated from the training school.

**The New York Clinical School of Medicine.**—Dr. Thomas H. Manley has been appointed professor of surgery.

**The German West Side Dispensary.**—Dr. Thomas H. Manley has been appointed a visiting surgeon.

**St. Joseph's Hospital.**—Dr. Alfons Müller has been appointed a visiting physician.

**The Death of Dr. George Harley, of London,** is announced to have taken place on Tuesday, the 27th inst. He was sixty-seven years old.

**Change of Address.**—Dr. Irwin Howell Hance, to Forrest Avenue, Lakewood, New Jersey.

**Army Intelligence.**—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 18 to October 24, 1896:*

BROOKE, BENJAMIN, First Lieutenant and Assistant Surgeon. The leave of absence granted him on surgeon's certificate of disability is extended one month.

EWEN, CLARENCE, Major and Surgeon. The extension of leave of absence granted him on account of disability is further extended one month.

KIEFFER, CHARLES F., First Lieutenant and Assistant Surgeon, is granted leave of absence for two months, to take effect upon the completion of his duties with the Third Artillery.

**Naval Intelligence.**—*Official List of Changes in the Medical Corps of the United States Navy for the Week ending October 24, 1896:*

ELLIOTT, M. S., Assistant Surgeon. Ordered to the Naval Laboratory and Department of Instruction, New York.

**Society Meetings for the Coming Week:**

MONDAY, November 3d: New York Academy of Sciences (Section in Biology); German Medical Society of the City of New York; New York Medico-surgical Society; Morrisania Medical Society, New York (private); Brooklyn Anatomical and Surgical Society (private); Corning, N. Y., Academy of Medicine; Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; Boston Society for Medical Improvement; St. Albans, Vermont, Medical Association; Providence, Rhode Island, Medical Association; Hartford, Connecticut, Medical Society; South Pittsburgh Medical Society; Chicago Medical Society; Cleveland Medical Library Association.

**TUESDAY, November 3d:** New York Neurological Society; New York Obstetrical Society (private); Buffalo Academy of Medicine (Section in Surgery); Elmira, N. Y., Academy of Medicine; Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Hudson, N. J., County Medical Society (Jersey City); Androscoggin, Maine, County Medical Association (Lewiston); Hampden, Massachusetts, District Medical Society (Springfield); Baltimore Academy of Medicine; Medical Society of the University of Maryland (Baltimore).

**WEDNESDAY, November 4th:** New York Academy of Medicine (Section in Public Health); Harlem Medical Association of the City of New York; Society of Alumni of Bellevue Hospital; Medical Microscopical Society of Brooklyn; Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot, Maine, County Medical Society (Bangor); Bridgeport, Connecticut, Medical Association.

**THURSDAY, November 5th:** New York Academy of Medicine; Brooklyn Surgical Society; Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-psychological Association; Obstetrical Society of Philadelphia; United States Naval Medical Society (Washington); Cuyahoga, Ohio, County Medical Society.

**FRIDAY, November 6th:** Practitioners' Society of New York (private); Baltimore Clinical Society; St. Louis Academy of Medical and Surgical Sciences.

**SATURDAY, November 7th:** Clinical Society of the New York Post-graduate Medical School and Hospital; Manhattan Medical and Surgical Society, New York (private); West End Medical Society of the City of New York; St. Louis Medical Society; Miller's River, Massachusetts, Medical Society.

## Births, Marriages, and Deaths.

### Born.

**GÜNTZER.**—In New York, on Wednesday, October 21st, to Dr. and Mrs. J. Henry Güntzer, a son.

### Married.

**BISSELL—GORDON.**—In Buffalo, on Thursday, October 22d, Dr. William Grosvenor Bissell and Miss Magdalene Gordon.

**BUCKLIN—WIGGIN.**—In Providence, Rhode Island, on Wednesday, October 21st, Mr. Edward Everett Bucklin and Miss Hope Wiggin, daughter of Dr. Chase D. Wiggin, of Mystic, Connecticut.

**BUTLER—JONES.**—In Rock Hill, South Carolina, on Wednesday, October 28th, Dr. W. F. P. Butler, of Edgehill, South Carolina, and Miss Lillian Jones.

**CABOT—BLAKE.**—In Portsmouth, New Hampshire, on Tuesday, October 6th, Dr. Follen Cabot and Miss Edith Tufton Blake.

**CHASE—DAVIS.**—In Pawtucket, Rhode Island, on Wednesday, October 21st, Mr. Howard Pearson Chase and Miss Mabel Maud Davis, daughter of the late Dr. Charles E. Davis.

**EATON—POTTER.**—In Buffalo, on Wednesday, October 28th, Mr. Lewis Eaton and Miss Fanny Potter, daughter of Dr. William Warren Potter.

**PAYNE—CORPENING.**—In Clarksburg, West Virginia, on Wednesday, October 14th, Dr. John Bosworth Payne and Miss Sallie F. Corpening.

### Died.

**BERGIN.**—In Cornwall, Ontario, on Thursday, October 22d, Dr. Darby Bergin, Surgeon-General of the Canadian militia, aged seventy years.

**HOLMES.**—In Portland, Oregon, on Wednesday, October 21st, Dr. Horatio R. Holmes, aged forty years.

**JONES.**—In Baton Rouge, Louisiana, on Friday, October 23d, Dr. Joseph S. Jones, aged forty-four years.

**MCCANN.**—In Boston, on Wednesday, October 28th, Dr. Charles F. McCann, of New York.

**MARTIN.**—In Augusta, Maine, on Monday, October 26th, Dr. George W. Martin, aged sixty-two years.

**PALMER.**—In Keansburg, New Jersey, on Tuesday, October 27th, Dr. Warren W. Palmer, aged sixty-eight years.

**PEACOCKE.**—In Brooklyn, on Friday, October 16th, Beatrice N., wife of Dr. J. M. Peacocke.

## Letters to the Editor.

### ABORTING GONORRHEA.

242 WEST FORTY-THIRD STREET, NEW YORK, October 24, 1896.

To the Editor of the New York Medical Journal:

SIR: Your leading article on the Abortive Treatment of Gonorrhœa, in to-day's issue, does not show such favorable results for the copious irrigation of potassium permanganate as Goldberg, whom you quote, produced in a previous paper, which appeared in the *Centralblatt für die Krankheiten der Harn- und Sexualorgane*. In that paper Goldberg collated the opinions of all who had written, favorably or otherwise, upon the method popularized by Janet. The results obtained were:

Cured within ten days.....	60 per cent.
“ “ two weeks.....	30 “
Failed because of transgressions in Baccho et Venere.....	5 “
Unexplained failures.....	5 “

Such statistics, into which even the writings of opponents of the method enter, are certainly better than those coming from any other manner of treatment. The principal reasons for its non-adoption by the profession at large have been, to my mind:

1. The cumbersome and expensive apparatus used by Janet, Frank, of Berlin, and others.

2. The uncleanness, which required covering the patient, the operator, and office floor with rubber gowns and sheets, to protect them from the sputtering of the solution, of which I was as guilty as those to whom I owe my beginning the method.

These objections have been set aside by the apparatus described by me in the *Clinical Recorder* for February, 1896. It is cleanly and easily managed and allows dealers to make a good profit at five dollars for the complete outfit. I now know of nearly two hundred physicians in America using the improved apparatus. Every day brings a large number of letters assuring me of their favorable results. I hope to compile these into statistical form when I have the complete records of at least ten thousand cases.

The method—I am not speaking of my irrigator, which is a mere convenient simplification—certainly enables us to cure, if we will but acknowledge it, ninety-eight per cent. of our cases of gonorrhœa within two weeks. I prefer to withhold more optimistic figures for the present. But the results are encouraging not only in acute gonorrhœa. In chronic gonorrhœa, with or without complications, Oberländer's urethroscopic and dilating method has given us, until now, the most favorable results. I shall attempt to show at the Pan-American Congress that when Oberländer's treatment is combined with hydrostatic irrigations we can safely promise to cure all our patients.

I shall be pleased to demonstrate these methods of

aborting gonorrhea and treating chronic urethritis to any of the many *New York Medical Journal* readers who will favor my class with a visit on Tuesdays, Thursdays, or Saturdays (at 3 P. M.) at the New York School of Clinical Medicine, No. 328 West Forty-second Street. Should you, Mr. Editor, find time to accept this invitation, I am confident you will, as the result of your own observation, think that these statements not only seem to make a remarkably good showing, but are exactly what the faithful followers of the method assert.

FERD. C. VALENTINE, M. D.

## Proceedings of Societies.

### NEW YORK STATE MEDICAL ASSOCIATION.

*Thirteenth Annual Meeting, held in New York, on Tuesday, Wednesday, and Thursday, October 13, 14, and 15, 1896.*

The President, Dr. DARWIN COLVIN, of Wayne County, in the Chair.

**Functionless Organs—Are there Any? A Possible Use of the Appendix Vermiformis.**—Dr. NELSON L. NORTH, of Kings County, read a paper with this title. He said that it was now coming to be understood that many organs formerly looked upon as rudimentary and functionless were really part of the hematopoietic system. Thus, the tonsils, which had been so freely excised in the past, were now considered as guardians of the parts below, protecting them from the invasion of pathogenic organisms. A noteworthy example of a supposed functionless organ was to be found in the vermiform appendix, but he was of the opinion that the numerous follicles of the appendix indicated clearly that it possessed a glandular action. Probably its chief function was as an automatic closer of the ileo-cæcal valve, thus preventing the regurgitation of foul gases. A study of the vital statistics of the Brooklyn Board of Health for the past fifteen years would show a steady increase in the death-rate from appendicitis and allied diseases, from which it was fair to infer that medicine had not kept pace with surgery in the treatment of these disorders. It was probable that the trouble was to be found in an improper treatment at their inception, the medical man of the present time throwing up his hands and unconditionally surrendering his patient to the operating surgeon. The intelligent and cautious use of mild purgatives and enemata, and above all the bold use of opium, not simply for its sedative action, but for its curative effect in peritoneal diseases, would, he felt confident, make a better showing in the treatment of appendicitis.

Dr. JOHN CRONYN, of Erie County, said that if at the very beginning of an appendicitis a calomel purge was administered, an ice-bag applied to the affected region, and a liberal dose of opium given, we should hear much less of failures in the medical treatment of this condition.

Dr. WILLIAM M. BEMIS, of Chautauqua County, said that the method of treatment outlined by the last speaker had proved successful in his own hands, although he had preferred to add one more remedial measure—the use of cold-water injections.

**The President's Address.**—Medical Expert Testimony was the subject.

The address dealt with the problem of how the present defective system of taking medical testimony might be improved. The president said that nothing was more degrading than to constantly hear the medical expert speak of "our side." It was because the medical expert was employed by one side, instead of being appointed by an independent power, far removed from all criticism and connection with the parties in litigation, that so many evils had crept into the present system. Not until the medical expert was so appointed, and paid liberally by a daily allowance that would attract the best talent, would the position become the honorable one that it should be.

**Prostatic Enlargement.**—Dr. J. W. S. GOULEY, of New York County, presented the opening paper in this discussion. He enumerated, as follows, the chief morbid states giving rise to an enlargement of the prostate: (1) Acute inflammatory action; (2) chronic parenchymatous prostatitis; (3) dilatation of the prostatic sinus; (4) retention cysts; (5) tuberculosis; (6) true adenomata; (7) fibrous tumors; (8) diffuse increase of the prostatic fibrous framework; (9) circumscribed multiple myomata; and (10) diffuse increase of the muscular tissue. Tuberculosis of the prostate, he said, was rare, but when it was present was apt to greatly augment the size of the prostate. Diffuse increase of muscle tissue constituted the greater part of the substance of some hard prostates. The morphological changes were: (1) Enlargement, limited to one lobe, or involving both lobes; (2) enlargement of the lobes unequally; (3) one or both lobes projecting into the bladder; (4) one or both lobes encroaching upon the prostatic region of the urethra; (5) the posterior third of the lower isthmus alone enlarged in the form of a round, pedunculated tumor or a sessile growth; (6) the whole of the lower isthmus alone enlarged; (7) both lobes and the posterior third of the lower isthmus enlarged; (8) both lower lobes and isthmi increased; (9) enlargement of both lobes downward and backward, overlapping the seminal vesicles; (10) a mere bar at the neck of the bladder, with but little general enlargement of the prostate; (11) intramural isolated tumors; (12) multiple tumors from one or both lobes projecting into the urethra, with or without enlargement of the posterior third of the lower isthmus; and (13) multiple tumors, with or without general enlargement, sometimes springing into the bladder from the posterior third of the lower isthmus and causing incontinence of urine.

The most common form—chronic progressive enlargement of the prostate—was, he said, a disease of elderly men pre-eminently, and was present to a greater or lesser degree in about forty per cent. of all men between fifty and seventy years of age. However, only about one in six suffered serious inconvenience from its interference with urination. A careful analysis of many of these cases would not fail to demonstrate the inflammatory origin and slow development of chronic enlargement of the prostate. An important part of the treatment consisted in irrigations of the bladder, and for this purpose he preferred either a 1-to-10,000 solution of corrosive sublimate, containing one per cent. of phenol, or a 1-to-1,000 solution of formalin. Where the bladder was very foul, it should be washed out in the morning with the sublimate solution and in the evening with a very weak solution of nitrate of silver. The use of metallic catheters, either by the patient or by the physician, was condemned. Early operative interference was justifiable as prophylactic of the lesions consequent upon stagnation of urine, but was contraindicated

when the upper urinary organs were seriously damaged. An operation should be resorted to in cases in which the bladder had been permanently contracted, when catheterism was extremely difficult or followed by rigors, or when self-catheterism was not possible. The chief operations were: (1) Suprapubic cystotomy; (2) the establishment of a suprapubic fistula; (3) dilatation of a false route; and (4) capillary puncture of the bladder. These measures, while only palliative, were often of the greatest value. Dilatation of a false route should be accomplished by means of a special instrument, called an "invaginated catheter." It was usually followed by spontaneous urination for about two years, and then, although catheterism would be required, it would be much easier of performance than if the operation had not been done. Capillary puncture of the bladder might be done once in an emergency, but its repeated performance had been proved to be ill-advised. Suprapubic cystotomy was to be considered the safer method where other modes of operation were not clearly indicated. Numerous surgeons had reported excellent results from the radical operation of suprapubic prostatectomy. A new method of performing prostatectomy, and one that was particularly applicable to the early stages, when there had been but little involvement of the bladder or upper urinary organs, had been devised and performed by Dr. S. Alexander, of New York. The chief advantages alleged for his method were: (1) The combination of the infrapubic and suprapubic section for purposes of exploration as well as for enucleation; (2) the rapidity with which the operation could be performed; (3) the slight and controllable hemorrhage during and after enucleation; (4) the slight injury inflicted upon the urethra and bladder; and (5) the maintenance of suprapubic irrigation and perineal drainage. This seemingly bold operation he looked upon as the greatest and best operation ever devised for performance upon the genito-urinary organs.

Dr. SAMUEL ALEXANDER, of New York County, continued the discussion. He said that the value of catheterism depended largely on the care with which it was done, and its inapplicability to individual cases should receive early recognition by the surgeon. A radical operation was required in the following conditions: (1) When there was complete or nearly complete retention of urine, due to outgrowths of the prostate, making the person constantly dependent upon the catheter; (2) when there was a marked and continuous vesical irritability, due to intravesical outgrowths; (3) when in spite of careful catheterism the amount of residual urine steadily increased; (4) when catheterism became more and more difficult, and was frequently followed by hemorrhage; (5) when catheterism, in spite of all precautions, was frequently followed by cystitis; (6) in cases of long-continued vesical inflammation, not yielding to other treatment; and (7) when the patients could not or would not use the catheter aseptically. A radical operation in these cases should not only immediately and completely remove the obstruction to urination, but should also establish efficient drainage of the bladder, and do all this without inflicting much damage upon the prostatic urethra. The disadvantages of McGill's suprapubic method, the one commonly employed in this country, were, that the mucous membrane covering the prostatic urethra was cut through and more or less contused, that the hemorrhage was apt to be so severe as to require packing of the wound, and that a cavity was left which, being accessible to the urine, might

prove a source of septic infection. Dr. Alexander said that his own method of performing prostatectomy had been first devised and carried out in January, 1894. He had operated in this way altogether eight times, with only two deaths. In all but one of the successful cases, the ability to evacuate the bladder completely had been restored. The great danger of the operation was the failure of the kidneys to perform their function. He had found that even the completely atonied bladder was capable of regaining its tone after years of obstruction, and that in most instances voluntary micturition could be restored.

Dr. W. G. BROWNSON, of Noroton, Connecticut, detailed his palliative method of treating prostatic enlargement in the old soldiers under his care. He preferred to use for washing out the bladder a 1-to-200 or 1-to-500 solution of carbolic acid and glycerin, injecting from two to four ounces into the bladder by means of a fountain syringe and a soft catheter, and keeping up each washing until the fluid came away clear. It was rare that more than one washing a day was required, and this simple treatment served in a large proportion of cases to keep the old men cheerful and comfortable.

Dr. DOUGLAS AYRES, of Montgomery County, said that one of the early effects of prostatic enlargement was to produce more or less residual urine, and that as a consequence of the decomposition of this urine the mucous membrane of the bladder was destroyed. Dilatation of the ureters and kidneys was a later result. It was important to remember that complete retention was one of the late symptoms. If these cases were seen early, the medical adviser could do much good by regulating the bowels, prescribing moderate exercise, with mild food and drink, attending to the proper protection of the surface of the body from chilling influences, and insisting upon a regular evacuation of the bladder. The quantity of residual urine should be determined early, and if it amounted to about two ounces and was sterile, the catheter should be used. The frequency of catheterism would depend upon the quantity of residual urine. The larger sizes of soft-rubber catheter were best for self-catheterism. At first, sterilized water at 100° F. would be found useful for irrigating the bladder.

Dr. H. O. MARCY, of Boston, thought that the perineal opening should be sufficient for drainage in cases of prostatectomy without using also the suprapubic wound, as Dr. Alexander had recommended. He predicted that this operation would have a wide range of usefulness, and would prove to be a brilliant addition to surgery.

Dr. GOULEY emphasized the importance of using only the finger or a blunt instrument in enucleating the prostate.

**The Treatment of Fæcal Fistula.**—Dr. FREDERICK HOLME WIGGIN, of New York County, read a paper on this subject in which he gave the histories of three cases. Two of the patients had been operated upon previous to coming under his care, but without success. He attributed the failure of the other operative procedures chiefly to the omission to thoroughly break up the adhesions of the bowel, which by their continuance kept up more or less intestinal obstruction, and so resulted in a giving way of the sutures and a reopening of the fistula. He had been greatly aided in this difficult field of surgery by the knowledge of a means of cleansing the peritoneum and preventing septic peritonitis in cases in which the contents of the bowel accidentally escaped into the peritoneal cavity. Three years

ago he had discovered that if this accident occurred, it was only necessary to wash off the peritonæum with a fifty-per-cent. solution of hydrozone in sterilized water, and follow this with a washing with saline solution, to thoroughly cleanse and disinfect the peritonæum without irritating it.

Dr. MARCY heartily indorsed the paper, and stated that in a number of instances of this kind he had felt that it was better to let the original opening alone, making the incision in the median line and dissecting off the adhesions of the intestine to the abdominal wound. He had found it very easy to close the opening in the intestine with a double tendon suture, after which, in order to have an additional safeguard and to prevent the formation of intestinal adhesions, he reflected over it the peritonæum by what he called a "continuous parallel suture."

**Irritable Stump.**—Dr. JOSEPH D. BRYANT, of New York County, read a paper on this subject. He stated that, according to the military statistics of the late war, of 287 amputations of the leg examined five months after the operation, in twelve per cent. the stumps were still unhealed, and in fourteen per cent. they were imperfect. Of 132 amputations of the thigh, according to the same authority, there were 21 unhealed and 21 with imperfect stumps at the end of the same period. So far as he had been able to ascertain from makers of artificial limbs and from a study of the subject, the three main requisites in securing a good and useful stump were: (1) Such a length of flap that undue traction would not be made on the stump; (2) a movable cicatrix; and (3) a periosteal covering for the divided ends of the bone. The first was the most important, because, if it was attended to, the evils of the others were reduced to a minimum. Dr. Bryant then described the method which he had found satisfactory in dealing with an irritable stump in the lower third of the leg. It was, briefly, as follows: A circular flap was made in the lower third of the leg, of a length a little greater than one fourth the circumference of the limb at the point of division of the bone. This flap was reflected upward for about half an inch, and then a transverse incision was made across the subcutaneous surface of the tibia, at the line of reflection of the flap, down through the periosteum. The periosteum was also divided by an incision in the long axis of the tibia. The periosteum was then pushed up instead of being dissected up with the flap in front. In this way a portion of flap corresponding to the subcutaneous portion of the tibia was lined with periosteum, and this fell over the end of the bone when the flaps were coaptated. The tibia was divided transversely on a line with the periosteal reflection, and the fibula a quarter of an inch higher up. The flaps were coaptated obliquely on a line with the subcutaneous surface of the tibia. It was important, Dr. Bryant said, that the periosteal flap should remain connected with the superimposed tissue, otherwise it would slough away or become absorbed.

Dr. MARCY said that one very common cause of irritable stump—the presence of a neuroma—could be largely avoided by covering over the nerve with periosteum. Where the various layers of tissue were closed by separate rows of sutures, it would usually be found that the stumps were more serviceable.

**The Hindrances to the Successful Treatment of the Diseases of Infancy and Childhood.**—Dr. J. LEWIS SMITH, of New York County, presented a paper dealing with some of the popular notions and fallacies that had in-

terfered with the progress of pædiatrics. Prominent among these was the artificial importance given to dentition as a factor in the production of the diseases of infancy. Unfortunately, the medical attendant had too often encouraged this notion in order to afford a cloak for his own ignorance in the diagnosis of such diseases. It was also a matter of common occurrence for parents, under the belief that "growing pains" were a part of normal growth, to postpone seeking medical advice until, as a result of the uncontrolled rheumatic process, the little one had become affected with rheumatic endocarditis and valvular lesions. It should be kept in mind that children often experienced at first but little discomfort from an attack of rheumatism, and that for this reason its true significance was prone to be overlooked.

**The Practical Uses of Roentgen's Discovery as Applied to Surgery.**—Dr. REGINALD H. SAYRE, of New York County, presented a communication on this subject, and demonstrated some of these practical applications by projecting on a screen some X-ray photographs of surgical cases. He said that the photographs taken by means of the X-rays, like those taken by ordinary light, varied considerably with the time of exposure. Thus, a certain time would give an excellent picture of the bones of the hand, but if this exposure was more prolonged, it would be found that the bones would be more or less indistinct or even invisible. It was possible, as illustrated by some of his lantern slides, to take X-ray photographs of a fractured limb while still incased in a plaster-of-Paris bandage, thus affording the surgeon an unparalleled advantage in the proper coaptation and management of fractures. By the same means, photographs could be taken of the pelvis, illustrating the position of the head of the femur in cases of congenital dislocation of the hip, before and after operation or mechanical treatment. In cases of true bony ankylosis, the X-ray photograph would not show the gap ordinarily seen between the ends of the bones, thus enabling one to readily distinguish between true and false ankylosis. As the tarsus in young children was cartilaginous, and translucent to the X rays, not much could be learned from X-ray photographs of the clubfoot of young children.

**The Treatment of Otorrhœa, and its Importance.**—Dr. EDWARD B. DENCH, of New York County, read this paper. He said that a profuse chronic purulent discharge from the ear which had lasted for more than two months evidently came from the middle ear, and, of course, the membrana tympani would be found perforated. If the purulent discharge was scanty, it was probable that its source was the external meatus. If the discharge was serous and not very abundant, it probably came from the middle ear. While pressure in front of the tragus or traction on the auricle in the adult would elicit pain in cases of disease in the external auditory canal, this sign did not hold true in children, because in them the bony canal was absent. Where the drainage was free, the discharge would cease as soon as all necrotic tissue had been discharged. The first object in treatment should be to maintain efficient drainage, and then keep the parts aseptic. The speaker preferred syringing out the ear to the use of gauze drainage. The process of syringing could be done thoroughly only when the precaution was taken to draw the auricle outward, upward, and backward in the adult, and outward, downward, and backward in the child. Peroxide of hydrogen should not be instilled into the ear in cases of purulent otorrhœa, because the solution was irritating

and the quantity of gas liberated when it came in contact with pus was apt to cause an injurious degree of pressure within the ear. The best solution for irrigating the ear was a warm 1-to-3,000 or 1-to-5,000 solution of bichloride of mercury. The patient should be cautioned against plugging the ear with cotton in the interval between the irrigations, as this practice was very apt to result in the formation of furuncles about the meatus. All forms of powders were objectionable in the ear, as they formed hard crusts with the discharge, thus obstructing drainage and irritating the ear. In conclusion, Dr. Dench quoted statistics, showing that out of 820 cases of suppurative disease of the middle ear, 2.5 per cent. had terminated fatally.

**The Relation of Affections of the Upper Air-Passages to the Diseases of the Ear.**—Dr. FRANK S. MILBURY, of Kings County, read a paper with this title. He said that, as middle-ear disease was frequently dependent upon stenosis of the nasal passages, it followed that intranasal surgery would often improve the hearing and sometimes relieve annoying tinnitus. Atrophic rhinitis, nasopharyngeal catarrh, enlargement of the tonsils, and adenoids in the pharynx were all responsible for more or less ear disease.

(To be continued.)

## Book Notices.

*System of Surgery.* Edited by FREDERIC S. DENNIS, M. D., Professor of the Principles and Practice of Surgery, Bellevue Hospital Medical College, etc. Assisted by JOHN S. BILLINGS, M. D., LL. D. Edin. and Harv.; D. C. L. Oxon.; Deputy Surgeon-General, U. S. A. Vol. IV. Tumors—Hernia—Surgery of the Alimentary Canal—Appendicitis—Surgery of the Liver and Biliary Passages—of the Uterus—of the Ovaries and Tubes—Gynecological Surgery—Symphysiotomy—Surgery of the Thyroid—Surgical Peculiarities of the Negro—Surgery of the Female Breast—Use of the Röntgen Rays in Surgery. Profusely Illustrated. New York and Philadelphia: Lea Brothers & Co., 1896. Pp. 7 to 970. [Price, \$6.]

The last volume of Dr. Dennis's work includes as contributors a list of celebrated writers such as has seldom if ever been found in a single volume upon surgery. The number is not large, but there is scarcely one among them who is not known in this country and in Europe as an authority upon the subjects of which he writes.

Dr. Dennis has associated with him in his opening chapter on tumors Dr. Edward K. Dunham, whose work in the Carnegie Laboratory eminently fits him to speak with authority upon the pathology of neoplasms.

Dr. Bull is assisted in the chapter upon hernias by Dr. William B. Coley, who has done much in recent years to perfect operative procedures in the treatment of these conditions. Perhaps no two men are better qualified to speak with authority upon this subject. The excellent results obtained in recent years by operations in these cases make this chapter one of great interest to both the practitioner and the student.

The chapters upon the surgery of the alimentary canal, by Dr. Richardson and Dr. Pilcher, are both

interesting and full of information, but why the two should have been separated by that upon the surgery of the spleen is not apparent to us.

"Appendicitis" is treated of by Dr. Hartley and Dr. McBurney, and this chapter needs no comment to those familiar with the literature of the subject. There are few cases of this disease ever treated, in this country at least, where Dr. McBurney's name is not mentioned in connection with the diagnostic "point" which he has established, and all readers will be glad to learn his latest opinions upon this subject.

The chapter upon the surgery of the liver and biliary passages, by Dr. Robert Abbe, is characteristic of this careful operator.

The section upon the surgery of the uterus, the ovaries, and the Fallopian tubes has most properly been assigned to gynecologists. Dr. Polk, Dr. Joseph Taber Johnson, Dr. Coe, and Dr. Lusk have contributed interesting and instructive chapters upon these subjects, and so far as the surgical part is concerned one need not go further than this volume to learn the proper procedure in any given case.

Dr. Weir has contributed a chapter on the surgery of the thyroid gland, and Dr. Matas one on the surgical peculiarities of the negro.

The volume and the work close with a discussion of the use of the Röntgen, or X, rays in surgery, by Dr. W. W. Keen.

This last volume seems to us the best of the four in Dr. Dennis's *System*, and a fitting conclusion to his monumental work. We congratulate him upon the happy outcome of his faithful and arduous labor, and commend the work to all investigators and teachers in surgery.

*The Pathology of the Contracted Granular Kidney and the Associated Cardio-arterial Changes.* By SIR GEORGE JOHNSON, M. D. Lond., F. R. C. P., F. R. S., Emeritus Professor of Clinical Medicine, etc. With Twenty-nine Illustrations. London: J. & A. Churchill, 1896. Pp. vi-62. [Price, \$1.40.]

THIS little book is the last from the pen of this well-known English writer, now deceased, in which he gives an historical summary of the long debate among pathologists on the causation of the cardio-arterial changes associated with chronic diffuse nephritis. The work has therefore a manifest historical interest, dealing as it does with the views of many old authorities most of whom are now dead. Naturally, the author writes with the intention of supporting his own views of the relation between chronic nephritis and arterial changes, and interprets the opposing arguments from his personal standpoint. Among the points specially emphasized, the following may be recalled with profit. The arterial changes of chronic nephritis are very general throughout the body, but do not affect the pulmonary vessels or the right side of the heart. The thickening of the renal arterioles is usually in the media; but of the pial vessels it is usually of the adventitia.

The term "arterio-capillary fibrosis" should be discarded, seeing that the capillaries in chronic nephritis are not affected by fibroid change. The thickening of the arterioles is not the result of inflammation, but represents a physiological hypertrophy which balances the excessive force of the left ventricle. "The pathological process in the kidney is neither primarily interstitial nor is it of the nature of inflammation, and it would be more correct to designate the cirrhotic kidney as the

atrophic granular kidney," in which the renal cells are the primary seat of the lesion.

*Occasional Papers on Medical Subjects. 1855-1896.* By W. HOWSHIP DICKINSON, M.D., F.R.C.P., President of the Royal Medical and Chirurgical Society, etc. London, New York, and Bombay: Longmans, Green, & Co., 1896. Pp. 247. [Price, \$1.]

SEVENTEEN papers written at various times during the past forty years are here brought together in one volume. The author's views and comments are very clearly put forth, and much of the interest in reading this book lies in the opportunity for comparison between the past and the present. The Practice of Medicine at St. George's Hospital Forty Years Ago gives a very vivid picture of what the patient had to contend with in those days besides disease. Mercury, antimony, bloodletting, and blisters were very common therapeutic agents. The writer concludes: "We may at least say this much for these latter days, that if he (the patient) die, he dies of the disease, not of the physician."

In one article is upheld the theory that the presystolic murmur is falsely so called, and is rarely a systolic mitral-regurgitant murmur. While this position is hardly tenable, much can be said to favor it, and the author presents a forcible argument in its behalf.

Other papers are devoted to counter-irritation, the morbid effects of alcohol as shown in patients who trade in liquor, the action of digitalis on the uterus, the pathology of chorea, hereditary albuminuria, cirrhosis of the liver in childhood, places and commonplaces in renal diseases, and the uses of alkalies in rheumatism. The book is well worth reading.

*Die Infektions-Krankheiten. Ihre Abwehr und Unterdrückung.* Von Dr. HEINRICH BERGER, Königl. Kreisphysicus in Neustadt a. Rhge. (Hannover). Braunschweig: Friedrich Vieweg und Sohn, 1896. Pp. viii-3 to 310.

In this monograph the author divides his work into two portions. The first part deals with the national, international, and local laws of quarantine against infectious diseases, the duties of boards of health, and the urgency of strict isolation in contagious diseases, and contains a discussion of the laws to secure it. The second part of the book takes up each infectious disease, with the usual clinical descriptions, but with particular reference to prophylaxis and to the prevention of the spread of the disease. Although the work is by no means noteworthy, the subjects are thoroughly treated of and discussed with evident knowledge. The book is well printed on very poor paper.

*The Stomach: Its Disorders, and how to Cure them.* By J. H. KELLOGG, M.D., President of the Medical Missionary College, Chicago. Illustrated. Battle Creek, Michigan, Chicago, New York, and London: Modern Medicine Publishing Company, 1896. Pp. 3-368.

THE author of this book intends it to be a "patient's guide" with or without the aid of a physician. We fail to see how it can possibly be useful to either. It is devoted to a description of the organs of digestion, of digestive processes, and of diseases of the stomach and their treatment. Twenty-six varieties of indigestion and their treatment are given. The treatment

includes the use of drugs, hydrotherapy, massage, diet, electricity, proper clothing, etc. We are told that many of the mixtures, appliances, and other necessities may be obtained from the Modern Medicine Company, Battle Creek, Michigan.

#### BOOKS, ETC., RECEIVED.

*A Text-book of Special Pathological Anatomy.* By Ernst Ziegler, Professor of Pathology in the University of Freiburg. Translated and edited from the Eighth German Edition by Donald MacAlister, M.A., M.D., Linacre Lecturer of Physic and Tutor of St. John's College, Cambridge, and Henry W. Cattell, M.A., M.D., Demonstrator of Morbid Anatomy in the University of Pennsylvania. Sections I-VIII. New York and London: The Macmillan Company, 1896. Pp. xix-575. [Price, \$4.]

*Alterations of Personality.* By Alfred Binet, Director of the Laboratory of Physiological Psychology at the Sorbonne (hautes études), Paris. Translated by Helen Green Baldwin, with Notes and a Preface by J. Mark Baldwin, Professor in Princeton University. New York: D. Appleton & Co., 1896. Pp. xii-356.

*Modern Greek Mastery. A Short Road to Ancient Greek.* By Thomas L. Stedman, A.M., M.D. New York: Harper & Brothers, 1896. Pp. viii-380.

*Recherches cliniques et thérapeutiques sur l'épilepsie, l'hystérie et l'idiotie. Compte-rendu du service des enfants idiots, épileptiques et arriérés de Bicêtre pendant l'année 1895.* Volume XVI.

*Naturwissenschaftliche Einführung in die Bakteriologie.* Von Dr. Ferdinand Hueppe, Professor der Hygiene an der deutschen Universität zu Prag. Mit 28 Holzschnitten im Texte. Wiesbaden: C. W. Kreidel, 1896. Pp. viii-268.

*The Clinical Importance of the Examination of Fæces.* By Julius Ullman, M.D., of Buffalo. [Reprinted from the *Buffalo Medical Journal*.]

*A Case of Tumor of the Thalamus, with Remarks on the Mental Symptoms.* By Walter Channing, M.D., of Brookline, Massachusetts. [Reprinted from the *Journal of Nervous and Mental Diseases*.]

*Mental Overstrain in Education.* By G. E. Shuttleworth, M.D., of England. [Reprinted from the *Lancet*.]

*Medicine as a Profession.* By Louis Faugères Bishop, M.D. [Reprinted from the *Rutgers College Tar-gum*.]

*A Report of Thirteen Cases of Multiple Neuritis occurring among Insane Patients.* By E. D. Bondurant, M.D. [Reprinted from the *Medical News*.]

*Pitting about the Hair Cups.* By William Brown-ing, M.D. [Reprinted from the *Journal of Nervous and Mental Diseases*.]

*The Prevention of Tuberculosis.* By E. B. Borland, M.D. [Reprinted from the *Journal of the American Medical Association*.]

*Further Observations of the Treatment of Spasmodic Torticollis.* By Maurice H. Richardson, M.D., and George L. Walton, M.D., of Massachusetts. [Reprinted from the *American Journal of the Medical Sciences*.]

*Does Science need Secrecy?* By Albert Lethingwell, M.D., of Cambridge, Massachusetts. [Reprinted from the *Boston Transcript*.]

*Some Affections of the Female Bladder.* By Edgar Garceau, M.D. [Reprinted from the *Boston Medical and Surgical Journal*.]

Some Thoughts concerning Disease and Recovery in their Relation to Therapeutics. By Solomon Solis-Cohen, M. D. Annual Address delivered before the Medical and Chirurgical Faculty of Maryland.

Pædiatrics; Past, Present, and Prospective. By S. W. Kelly, M. D., of Cleveland. [Reprinted from the *Cleveland Medical Gazette*.]

Nasal Affections as a Cause of Headaches. By J. H. McCassy, M. D., of Dayton, Ohio. [Reprinted from the *Cincinnati Lancet-Clinic*.]

The Diagnosis of Substances passed from the Bowels. By George F. Laidlaw, M. D. [Reprinted from the *Chironian*.]

A Critical Study of a Few of the Changes found in the Fields of Vision, taken while the Eyes are placed at Right Angles to their Ordinary Position. By Charles A. Oliver, M. D. [Reprinted from *Brain*.]

Diagnosis of Tumors of the Brain. By J. T. Eskridge, M. D. [Reprinted from the *Colorado Medical Journal*.]

The Diagnosis of Chronic Abscess of the Brain. By J. T. Eskridge, M. D. [Reprinted from the *American Journal of the Medical Sciences*.]

The Mortality of Suicides. Published by the Mutual Life Insurance Company.

## Miscellany.

**Thymus Feeding in Exophthalmic Goitre.**—In the *British Medical Journal* for October 10th Mr. David Owen records the following case of exophthalmic goitre of twenty years' duration, in which thymus feeding was followed by restoration to health: The patient first came under observation in May, 1893. Ordinary remedies were tried, but without benefit. After he had taken raw thymus, obtained from the lamb, in doses of about a quarter of an ounce daily for three months, the cardinal symptoms disappeared, and the patient was able to work better than he had done for years. The treatment was discontinued in January, 1894. Three months later there was a return of goitre, tachycardia, and slight exophthalmia. He then resumed the thymus, taking half an ounce or more of the raw gland three or four times a week. By July, 1894, the eye symptoms and goitre had quite disappeared, the pulse was 72, though before treatment it was constantly over 120. He had greatly gained in flesh, felt quite well, and was able to work twelve hours a day as a laborer. The following autumn he found himself unable to take the gland any longer, on account of its nauseating effects. At the end of three months he complained of increasing weakness, and expressed a fear that the old disease was returning. He then again resorted to the thymus, taking it for two months, but this time with no benefit. This was very disappointing, says the author, but as he remembered that the lambing season corresponded with the spring, it occurred to him that the failure of the glands might be due to their having been taken from older sheep than before, so it was resolved to give calf's thymus a trial, as lamb's was not obtainable. On March 22, 1895, the patient was worse than he had been before, and suffered from intense dyspnoea; the thyroid was large and pulsating, and there was violent throbbing of the carotids. The action of the heart was extremely tumultuous and

irregular, and the pulse was over 140. There were marked tremors of the hands, especially the left, and the whole body was much emaciated. The same night he took about half an ounce of calf's thymus, and repeated the dose in the morning. During the following week he improved astonishingly. On March 23d he felt much better, his breathing being much relieved. On March 26th, the pulse was 126, but the action of the heart was not so thumping and irregular as before, and the dyspnoea was improved. On March 28th the patient felt still better. Exophthalmia was decidedly less marked, pulsation in the neck scarcely visible, and goitre much diminished, tremors were less pronounced, the pulse was 104, the heart quiet and more regular, and no dyspnoea. Dr. E. J. W. Carruthers, who had seen the patient just before the calf's thymus was given, on seeing him a week later, was surprised at the remarkable improvement which had taken place in so short a time. The next three months the patient spent mostly in bed, and gastro-intestinal trouble prevented him from taking the thymus, except occasionally. Still, he gradually improved, and by October, 1895, suffered only from debility and emaciation. The improvement continued during the winter, but there was a return of symptoms this summer. He now suffers from occasional palpitation, sense of weakness, and low spirits, and there is some prominence of the eyes. There are, so far, no goitre or tremors, and he is fairly well nourished. The patient is not nearly so well as he was two years ago, but it must be noted that during the last eighteen months he has taken much less thymus than before on account of its nauseating effects, and for nine months has had none at all.

Since the author's communication on this subject appeared in the *Journal*, others have published confirmatory results.

Mikulicz found that nine out of ten patients with ordinary goitre were improved by thymus, and in a case of Graves's disease he noted improvement in palpitation, dyspnoea, and attacks of threatened suffocation. The exophthalmia and tachycardia were likewise diminished, but the goitre and tremors remained the same. The dose given varied, roughly speaking, from half an ounce to an ounce of the raw gland.

Maude, whose previous writings on Graves's disease enhance the value of his testimony, has tried the thymus treatment in four cases of this disease with most gratifying results. All the patients were benefited. In one case of an extremely aggravated form, which had been under observation over eight years, no drug, not even belladonna in large doses, had ever produced any effect. Under the use of thymus tabloids (forty-five grains *per diem*) the patient rapidly improved, but always relapsed when they were discontinued. The author states that he can quite indorse Dr. Maude's observation that the tremors are particularly relieved by this treatment. This fact so impressed him a year ago that he tried fresh thymus in a case of paralysis agitans, with the result that the tremors were unmistakably benefited, and the mental state and the muscular condition were greatly improved. The patient felt so much better, and his spirits were so buoyant, last Christmas that he astonished his family by "letting in the New Year" himself, a practice which he had always observed before his illness, but had been obliged to omit for years.

C. Todd, in the *Journal* of July 25, 1896, shows clearly how a patient with this disease, who had been treated in Shoreditch Infirmary for four months with-

out benefit, was immensely improved at once by thymus tabloids. An irregular pulse became quite regular, as shown by tracings in three days, and pulse-rate was reduced from 156 to 72 in three weeks. Discontinuance of the treatment caused the pulse to become irregular again, but on resuming the thymus the irregularity ceased.

Watson Williams has recorded a case in which thymus feeding apparently aggravated the tachycardia and pyrexia, but improved the general nutrition, the body weight being increased by four pounds in a week. It is rather doubtful, says Mr. Owen, whether the aggravation of symptoms was due to the treatment, as the pulse-rate was much higher when only thirty grains *per diem* were being taken than when half an ounce was the daily dose. The temperature also reached a higher point a week after the thymus was stopped than it had done while the treatment was being carried out.

The relief obtained in these cases must have been more than a coincidence, he says, as in one of his cases and in several recorded by others, discontinuance of the use of the gland was followed by relapse, but on resuming it the patients again improved.

The thymus, spleen, and other lymphoid structures have been often found hypertrophied in this disease. Hypertrophy or "revival" of the thymus has been observed by Möbius, Marie, Johnston, Hale White, Mossler, Spencer, and several others. Joffroy asserts that the latter condition occurs almost exclusively in exophthalmic goitre.

In view of the fact, says the author, that exophthalmic goitre is probably due to excessive activity on the part of the thyroid gland, it is of interest and importance to find evidence of antagonism between it and other ductless glands. Dr. George Oliver has lately shown that the thyroid and adrenals have an opposite action to one another upon the circulation, and has found that the curve of blood pressure produced by splenic extract differs from that of thyroid. The action of the thymus has not yet, Mr. Owen believes, been investigated, but in some respects, at least, it appears to be opposed to that of the thyroid. The administration of thyroid extract is often followed by loss of weight. On the other hand, the facts that the thymus is normally present during infancy only, when for the purpose of growth the necessity of minimizing waste is obvious, and that it is persistent in hibernating animals, undergoing enlargement at the approach of each hibernation, suggests strongly that this gland has an inhibitory influence over waste. This inference is supported by Demme's case, quoted by Jacobi, of a child which underwent rapid emaciation, dying on the forty-second day. Necropsy revealed no change in any other organ except the thymus, whose tissue was dense and contained three tubercles. Further confirmation is afforded by the experience of Friedleben, who saw a dog die of exhaustion, in spite of a voracious appetite, after extirpation of the thymus and spleen. In all of the author's cases a gain of flesh accompanied the disappearance of symptoms.

Some facts also suggest the possibility of an antagonism between the thymus and thyroid in their relationship to the nervous system. The thyroïdal secretion directly or indirectly has a stimulating influence over the cerebral functions, as is shown by their undeveloped condition in cretinism, and their degeneration in myxedema and after thyroïdectomy, and also by the effects following the administration of thyroïd

extract in cases of cretinism. There are reasons, says Mr. Owen, too, for believing, as pointed out by Freund and Horsley, that the activity of the thyroid gland is increased when active changes are taking place in the sexual system. On the other hand, during hibernation, when the thymus attains its greatest size, the cerebral and sexual functions are suspended, and in infancy are undeveloped, but undergo rapid development at puberty, when the thymus finally disappears. These facts, he says, suggest a functional relationship between the different ductless glands, and lead one to think that disease may result from disturbance in the balance of their internal secretions which might be remedied by suitable animal extracts.

**The Treatment of Erysipelas with Vaseline.**—The *Therapeutic Gazette* for October 15th says that, according to the *Therapeutische Monatshefte* for June, Dr. Koester treats erysipelas in the following manner: Vaseline is applied to the affected and surrounding parts twice a day; linen is laid over the vaseline, and a mask is made if the part affected is the face. The dressing is held in place with gauze bandages. In other respects the treatment is symptomatic—acetanilide or antipyrine for severe headache, and the same remedies, or quinine, when the temperature rises above 100° F. Ice-bags are applied to the head, and laxatives, chloral, digitalis, and alcoholics used as indicated. The advantages of this method are the following: It can be used even upon the hairy scalp; smarting, burning, and disagreeable odors are avoided; and the remedy is cheap.

Koester has employed the vaseline treatment in one hundred and thirty cases and maintains that the results are just as good as with some other remedies. He goes into an elaborate comparison of the vaseline treatment with other methods, considering in this comparison the general infection, especially shown by the temperature, the local process, and the complications.

As regards the fever, his table shows that of two hundred and eighteen cases not less than two hundred and five, or more than ninety per cent., were free from fever after six days' treatment, and one hundred and fifty-eight, or more than seventy per cent., were free from fever after four days. This is a better showing than that which followed treatment with lead water, ichthyol, corrosive sublimate and vaseline, and iodine.

As regards the second consideration, the local process, it appears that in thirty-six patients treated with lead water there was further extension in twenty-five per cent.; in fifty-seven patients treated locally with iodine, extension occurred in 10.5 per cent.; in twenty patients treated with ichthyol vaseline, extension occurred in thirty-five per cent.; in sixteen patients treated with sublimate lanolin, extension occurred in 12.5 per cent.; while in one hundred and twenty-eight patients treated with vaseline alone the percentage of cases in which further extension occurred was twenty-four. Koester argues against the apparently very favorable showing for the iodine treatment; he thinks extension occurred oftener than the notes indicate.

As regards the third consideration, the occurrence of complications, the results were as follows: In four patients not subjected to any treatment, phlegmonous processes recurred in four per cent.; in thirty-five patients treated with lead water, in 8.5 per cent.; in fifty-six patients treated with iodine painting, in seven per cent.; in twenty patients treated with ichthyol vaseline, in twenty per cent.; in sixteen patients treated with sub-

limate lanolin, in 6.5 per cent.; and in one hundred and thirty patients treated with vaseline the percentage of cases in which phlegmonous processes recurred was 11.6.

Dr. Koester, says the writer, reaches no conclusion in regard to the utility of vaseline, except, of course, that it has no antiseptic properties. He believes that the principal thing in the treatment of erysipelas is the treatment of the general condition. So long as the symptoms are insignificant, regulation of diet and maintenance of strength only are demanded. If the symptoms become more violent, if the fever increases, if delirium occurs, and if the strength diminishes, then appropriate remedies should be given, and the result is generally favorable. Dr. Koester does not maintain that this treatment is a new conception. On the contrary, he states that Trousseau, Vierordt, and Struempell hold the same opinion.

**Serpent Venom and Antivenomous Serum.**—In the *British Medical Journal* for October 10th Dr. A. Calmette states that, contrary to the opinion put forward by certain physiologists up to the present time, it is perfectly certain that the venoms of different species of snakes produce physiological phenomena which are in general alike. The only difference is in the local action of these venoms, and it is possible to separate artificially the substances which produce the local phenomena from those which cause bulbar intoxication. This dissociation can be effected by means of heat. If one heats to 185° F. for fifteen minutes any venom in solution in water, the albumin contained in this water coagulates, and the thermogenic substances are destroyed, while the toxicity of the venom itself is no way affected. M. Phisalix and M. Bertrand had previously demonstrated this fact as regards the venom of the French viper.

After heating to 185° F., and after filtration, all venoms produce the same effects, whether they are taken from viperine or from colubrine snakes. They differ from one another only in the inequality of their toxic activity. All are equally destroyed by alkaline hypochlorites and by chloride of gold—substances which the author suggested (particularly hypochlorite of calcium in 1-in-60 solution) for local use in preventing the absorption of venoms.

Quite recently M. Phisalix, assistant in the Paris Museum, announced that he had succeeded in isolating a vaccine substance by filtering venom through a Chamberland filter. The animals in which this experimenter inoculated filtered venom did not die, and were found to be "vaccinated" against the inoculation of a fatal dose of unfiltered venom. The author has repeated these experiments with the greatest possible care, but the results which he has obtained are very different.

When a solution of normal venom is filtered through Chamberland's apparatus much of it is held back by the porcelain, exactly as is the case with the microbial toxins. As a matter of fact, the lethal dose of filtered venom is two and a half times that of unfiltered venom. But if, before filtration, care is taken to precipitate the albumin in the venom by means of heat, it is found that the porcelain holds back scarcely any of the toxic substance. Animals are killed by the same doses of the solution before and after filtration. It follows, then, without doubt that if non-dealbuminized venom is less toxic after filtration than before, this must be due to the fact that the albumin adheres to the porous wall of the filter, and forms an actual dialyzing membrane through which the venom can pass only with the utmost difficulty.

Dr. Calmette states that he has proved this fact by replacing the albumin by means of a little normal serum in venom dealbuminized by heat. If this albuminous venom is filtered anew it will be found that the liquid which passes through the filter is much less toxic.

Animals which have survived filtered venom can tolerate some three days later a minimal mortal dose of venom without dying. They begin to be "vaccinated," just like those into whom a dose of normal venom less than the mortal has been injected. In the author's opinion, therefore, there is no need to suppose that by heat or by filtration of venom there is, as Phisalix and Bertrand suppose, a dissociation of two substances—the one toxic, the other antitoxic—which are found together in normal venom. This hypothesis appears to him to be in no way justified, and it is absolutely certain that if venom the toxicity of which has been reduced by heat or by filtration is injected into an animal in a quantity sufficient to kill it, the course of events will be precisely the same as if it had received the dose of normal venom slightly inferior to that which would have caused death. In both cases and in the same time the animal acquires by this inoculation resisting power, which permits it, even after several days, to tolerate with impunity a quantity of venom sufficient to kill other animals of the same weight.

The serum of animals "vaccinated" against a very active kind of venom, as, for instance, that of the cobra di capello, is perfectly antitoxic in respect of the venom of all other kinds of serpents, and even, says the author, as he recently proved, in respect of that of scorpions. Dr. Calmette insists upon this statement because it has recently been contested by Dr. Cunningham, and he states that he is ready to repeat before a commission the experiments which he has made many times on this subject.

The best method of "vaccination" in large animals which are to produce antivenomous serum consists in injecting into them at first increasing quantities of the venom of the cobra di capello mixed with decreasing quantities of a 1-in-60 solution.

All the observations in which the kind of serpent has not been determined must therefore be regarded as doubtful. He has published a most conclusive case relating to an Annamite who was bitten in the hand by a cobra di capello at the bacteriological laboratory of Saigon, who was cured by a single injection of ten cubic centimetres of serum.

It is proved conclusively, therefore, continues Dr. Calmette, both by experiment upon animals, and by the applications which have already been made in man, that we possess in antivenomous serum a specific remedy which is most efficacious in cases of venomous bites, and no time should be lost in spreading it throughout all countries in which there are poisonous reptiles.

**Antistreptococcus Serum in the Treatment of Puerperal Fever.**—In the *British Medical Journal* for October 10th Mr. R. G. McKerron relates the histories of three cases in which this treatment was employed, and states as his reason for recording them that the results in all cases, whether successful or not, should be put on record in order that the true position and value of the treatment as a therapeutic agent may be established early.

The evidence in these cases, he says, is, on the whole, favorable, although the exact effect of the injections is difficult to estimate, as always in the case of a new

remedy in a disease of uncertain and variable course. Two beneficial effects uniformly followed their use—a steadying of the pulse and an improvement in the subjective condition of the patient. The results would, he is convinced, have been more satisfactory had an earlier resort to the serum been possible. Whether a large dose and greater frequency would have influenced the results must be left to increased experience to determine. In a case of puerperal fever where the serum was used, which was recorded in the *British Medical Journal* of June 20th, a single injection was sufficient to reduce the temperature permanently to normal. The serum used in all three cases was from the Pasteur Institute.

**Ambulance Dogs.**—A writer in the *Union médicale* for September 19th remarks that in the streets of the village of Lechensch, near Cologne, there may be seen a veritable battalion of dogs which have been trained for the ambulance service in view of the approaching German military manoeuvres. Each animal carries on its back a small basket provided with pockets which contain all that is necessary for use in temporary dressing, also a flask of brandy. The dogs have been taught to recognize wounded persons and to lower the basket so as to enable them, while waiting for the litter, to quench their thirst and to relieve their sufferings. A large red cross is marked on the basket, and a small lantern with a reflector for night service is strapped on to the animal. These dogs took part in the German military manoeuvres last year, when their usefulness was demonstrated. This year their instructor has been charged with the training of another pack, for which he has chosen Scotch dogs of medium size, the intelligence and docility of which are remarkable.

**Thyroid Treatment in Lichen.**—The *Gazette hebdomadaire de médecine et de chirurgie* for October 8th contains an account of a recent meeting of the Pædiatric Society of Moscow at which Dr. Kissel related the following case: The patient, a girl ten years old, presented patches of a regular spherical form, which were covered with silvery white scales. These patches were spread over the entire body, more especially on the dorsal surface of the feet and hands, and on the anterior surface of the arms and the legs. Two thyroid tablets a day were prescribed for the child. The pruritus increased at once, as well as the desquamation of the patches, which, however, became of a lighter color. Afterward, when the doses were increased to four tablets a day, headache and vomiting were observed, but no rise in temperature. The treatment was continued and the doses were increased to six tablets a day, and little by little the eruption diminished and finally completely disappeared. During this time the child took two hundred and twenty-five tablets, each of which contained two grains and a quarter of the dried thyroid gland. Apart from headache, the patient felt very well during the treatment, and her appetite was good. Her weight did not increase. The urine was thick and contained a considerable quantity of sugar, but no albumin.

**The Serum Treatment in Ozæna.**—According to the *Presse médicale* for October 10th, the *Archivio italiano di ologia*, 1896, No. 3, publishes an account of some experiments made by Arslan and Catterina with injections of antidiphtheritic serum in eight patients who suffered from ozæna. In the secretions and in the mucous membrane of the nose in every patient the authors found the Lowenberg-Abel bacillus associated with the

bacillus which has recently been described by Belfanti and Della Vedova. From the first injections it was ascertained that the serum exercised an almost specific action on the pituitary gland; the congestion of this gland and the epistaxis which followed the injections proved that. In the beginning there was an amelioration, which consisted in the diminution of the secretions and of the odor. This modification, however, was only temporary, and the patients very soon relapsed into their former condition. Up to the present time, says the writer, the authors have not observed a single case in which recovery took place, which is contrary to the observations of Belfanti and Della Vedova.

**Vegetable Milk.**—In *Lyon médical* for October 4th there is an abstract of an article from *Médecine moderne* for September 9th in which the writer states that Lachmann's vegetable milk, when prepared with the help of almonds and sugar, does not contain any starchy substances and has a sufficiently large quantity of emulsified fat. Its composition is as follows:

Fat.....	24.60 per cent;
Vegetable casein.....	7.50 "
Cane sugar.....	41.80 "
Vegetable dextrine.....	1.30 "
Lime, potassium, etc.....	0.68 "
Water.....	24.12 "

This vegetable milk may be used to dilute cow's milk which is too rich in albuminoids. For this purpose it is superior to water, as it does not precipitate the casein in large flakes, but in small and soft ones. Furthermore, the addition of vegetable milk to cow's milk increases the fatty substance of the latter and accelerates its digestion. It contains the potassium and sodium salts which are so necessary for the constitution and the development of the infantile organism.

Dr. Hock, says the writer, employed the vegetable milk in thirty-one cases in which the infants were deprived of the mother's milk, with the following results: Six of them died; in twenty-three a notable increase in weight was observed; in three the rate of increase was forty-five, seventy-five, and a hundred and five grains a day, respectively; in the rest it ranged from two hundred and twenty-five to eight hundred and fifty grains a day. Such an increase, he remarks, is met with only in well-nourished breast babies.

**Large Injections of Saline Solution in Hæmorrhages and Infections.**—In the *Gazette médicale de Paris* for September 26th there is a long and comprehensive article on this subject by M. André Chaisse, of which the following is the substance: Fresh human serum, says the author, in a sufficient quantity, is not usually at our disposal, and the serum of animals can not be used, because of its toxic properties, therefore we must resort to artificially prepared liquids. The first requisite in regard to these solutions is that they must not alter the histological elements of the blood, except in a very small degree; for this reason distilled water is rejected. One of the following solutions may be employed:

1. Distilled water..... 31 ounces;  
Sodium chloride..... 105 grains;
2. Distilled water..... 31 ounces;  
Sodium chloride, ( each..... 105 grains.  
Sodium sulphate, (

The solution should be clear and without any foreign substance; it may be sterilized by being submitted to a temperature of 248° F. or to a boiling of twenty

minutes' duration. It should be injected at the temperature of the body, and, as it loses several degrees during manipulation, it should be kept in a funnel at a temperature of about 104°.

With regard to the rapidity of the injection, says M. Claisse, it is not here a question of the rapidity of toxic action fixed by Dastre and Loyer in the rabbit and in the dog; this rapidity was established for lavage of very long duration with unusual quantities of liquid in man. In this case an injection of forty-seven ounces, with a duration of ten minutes, did not cause any symptom of intolerance; therefore the rapidity (from thirty-three to forty-five grains, or three cubic centimetres, a minute) in these conditions is not toxic. It does not seem well to inject more than forty-seven ounces at a time; the reactionary symptoms will manifest themselves with this quantity. Occasionally, however, it is necessary to renew the injection several days in succession. Lejars successfully injected as much as seven pints in seven hours and twenty-six pints in nine days. The author thinks, moreover, that these enormous quantities are not often necessary. Four pints in twenty-four hours, he says, is the maximum quantity, to which we should limit ourselves; it is especially in cases of grave acute anæmia that we are warranted in exceeding this quantity sometimes to a great degree.

The results following these large injections, says M. Claisse, in subjects who are in a condition of shock or of acute anæmia, are striking. They seem to actually bring to life the bloodless patients in whom there is hardly any pulse, with no respiration, in whom the extremities are cold, pale, and deprived of all sense of feeling. The amelioration often shows itself as soon as the first three or four ounces of the solution are injected; the pulse becomes perceptible and respiration easier. Afterward arterial pressure becomes normal, the beating of the heart is regulated, the sense of feeling returns, the lips regain their color and the eyes their brightness, and the extremities become warm, although a slight chill sometimes occurs. In certain cases, when the amelioration is only temporary, the patient relapses, and a second injection may reanimate him, sometimes definitively.

The results obtained are too numerous to recount, especially in the treatment of acute anæmia, and the author simply calls attention to the recent observations of operation shock which have been published by Lejars, Duret, and Jayle, in which the effects of intravenous or subcutaneous injections were very favorable.

With regard to their mode of action, continues M. Claisse, it may be explained very simply in cases of acute anæmia as follows: The gravity of this condition depends especially upon a more or less rapid fall of the arterial pressure, owing to the deficiency of repletion of the circulatory system; the cardiac reflex is badly excited; the heart contracts irregularly and feebly, on a vacuum, so to speak. As soon as the blood-vessels are filled the heart regains its vigor and the arterial pressure rises rapidly; everything then returns to the proper order, the anæmia of the nervous centres disappears, and all the functions become normal.

The coagulant action of the intravenous injections has been established experimentally. They act as a hæmostatic by a double mechanism; they excite constriction of the ruptured arterioles, and especially accelerate in this respect the precipitation of the hæmatoblasts, the centres of the formation of clots; that is, they contract the orifice and favor the formation of a plug.

In the infections, the mode of action is a much more

delicate question to decide, as it is still surrounded by obscurity and far from being settled. It has been attributed to elimination of the toxins and of the bacteria by some kind of mechanical action or by the emunctories, the activity of which is brought into play; a veritable lavage of the blood. In reality, says the author, the problem seems to be a very complex one. Here it is not merely simple lavage of the blood. On the one hand, the quantity of liquid employed is insufficient to allow of a comparison between this method and that employed by Dastre and Loyer in altogether different conditions; on the other hand, may there not be a similar elimination of the noxious elements; is there not really toxuria? We are tempted to think so, he says, in view of the profuse diuresis which is often established; but this polyuria (or the diarrhœa which may replace it) frequently does not appear until several hours after a manifest amelioration. Besides, it is not at all established that the eliminated urine will then be more toxic or even more charged with albuminoid substances than before.

Finally, if these injections act simply by the polyuria which is produced by the increase of the arterial pressure, we should not observe these rapid and peculiar modifications. Concerning the elevation of the arterial pressure also, it is certainly important, but it may be as much an effect as a cause of the general amelioration.

Concerning the indications for this treatment, says M. Claisse, if there is a tendency to syncope which may endanger the patient's life, consequent on profuse hæmorrhage from any serious traumatism, accidental or operative, there must be no hesitation; the best treatment is intravenous injection; it is preferred in such cases because its action is certainly more rapid. The subcutaneous injections are sufficient in less serious cases. From one and a half to two pints of liquid are employed, although with a certain amount of caution, in order to avoid a reflex visceral congestion.

In infections and grave intoxication the injections are equally indicated; when the temperature rises above 102.5° F., and this rise indicates an alarming morbid process and not a temporary reaction, especially when the general symptoms reveal a grave pathological condition, this treatment should be employed, in combination, of course, with the usual local treatment.

As to the contraindications, says M. Claisse, there are none in cases of acute anæmia or of traumatic or operative shock; it is the only method of treating efficaciously a dying person. In infections the condition of the kidneys, the heart, and the lungs must always be watched. There is, perhaps, danger in injecting suddenly a large quantity of liquid in a subject in whom the kidneys are profoundly altered, who can not eliminate the excess of water introduced, inasmuch as the vascular system is then more or less disturbed and more easily distended, and when the heart is weak. In these cases we must act slowly and cautiously, and employ preferably the subcutaneous method. If there is œdema of cardiac origin, with excessive arterial tension, it is still more necessary to exercise prudence in employing intravenous injections. In this treatment, says M. Claisse, we have an agent which, logical in theory and based on experimentation and on clinical facts, may give the most favorable results in cases which seem beyond the reach of medicines.

In the *Therapeutic Gazette* for October 15th there is an abstract of an article from the *Médecine moderne* for May 13, 1896, in which it is stated that Lejars reported

to the Société de biologie three cases in which this treatment was used by him with the most favorable results. He believes that these injections are of the utmost value, and that the great difficulty is that they are not used in sufficiently large amounts. In ordinary conditions subcutaneous injections are sufficient, but where the condition is urgent the intravenous method should be employed. It is necessary, however, for the success of the treatment that the kidneys should be able to eliminate the infectious materials with the liquids. In two cases which he knows of, the kidneys did not excrete the liquid, and at the autopsy they were found to be in a condition of sclerosis.

Osusoff, says the writer, does not believe that a complete explanation of the value of these injections can be offered, but he insists upon their practical utility.

#### Erysipelas Serum in the Treatment of Carcinoma.—

Dr. W. A. Thiele (*Annalen der russischen Chirurgie*, 1896; *Centralblatt für Chirurgie*, October 3, 1896), on the strength of four cases of his own and a case of Emmerich's in which Emmerich and Scholl's erysipelas serum was used, comes to the following conclusions: 1. Complete cure with the serum has not been demonstrated. 2. The injections are free from danger, but not from inconvenience, for they occasionally give rise to headache, weakness, fever, etc. 3. The cancerous nodules grow smaller and occasionally disappear, and ulceration is checked. 4. Where an operation is impracticable, the serum should be used, for it mitigates the pain and thus takes the place of narcotics. 5. It is very desirable that the remedy should be employed systematically in cases of incipient malignant tumors, for in this way alone can its real value be determined.

**Serum Treatment in Pulmonary Phthisis.**—In the *Progrès médical* for October 10th M. Regnier gives a detailed account of a series of seven cases in which he employed this treatment with favorable results. He also gives a table of statistics concerning the observations, including the histories of 325 patients, which were recently published by Professor Maragliano. It comprises four series divided into sections as follows: Phthisis with cavities and fever; phthisis with microbial associations; diffuse febrile destructive phthisis; and phthisis without fever. The results obtained in these cases with the serum were as follows: Remained stationary, 50; ameliorations, 140; good results, 45; no results, 25; deaths, 14.

In the microbial form and in destructive phthisis of rapid progress the results were not so good. In the apyretic form, even with cavities, the serum appears to exert a true therapeutic power, says M. Regnier, and it may be said, with M. Roger, that in proper doses it is not at all dangerous. But, with regard to its efficacy, the author thinks he may go further and say that this serum is one of the most active medicaments which we have at our disposal to combat pulmonary tuberculosis.

The same journal contains a review of an article on this subject which is published in the *Archivio internazionale di medicina e chirurgia*, 1896, page 51, by Dr. Fasano. The writer states that Dr. Fasano employed Maragliano's serum in the treatment of pulmonary phthisis in the hospital of Sainte-Marie de la Paix. The patients were carefully watched by him every day and all forms of phthisis thoroughly studied. Maragliano's method was rigorously carried out in regard to the diet, the doses, and the time of injection, and the results obtained led the author to the following conclusions: 1.

The serum is absolutely harmless and does not provoke lesions of the renal organs. 2. In certain subjects there are some cutaneous manifestations, but they disappear rapidly. 3. Occasionally the serum produces engorgement of the ganglia near the seat of injection, but this may be avoided by a rigorous antiseptic during the procedure. 4. The serum has certainly an antithermic power, which varies with the temperature and the amount of serum injected; the lower the temperature the smaller should the dose be; when the temperature is higher the dose must be increased; a thermic lowering is obtained with five cubic centimetres, but the fever does not entirely disappear until after from twenty-five to forty injections have been given, according to the individual. 5. The serum diminishes respiratory action and the frequency of the pulse, as it causes a moderated action of certain nervous centres. 6. It increases the weight, the dynamometric strength, and the appetite from the beginning of the treatment. 7. It increases respiratory power and invariably diminishes the sweats, and in certain cases causes their complete disappearance. 8. The direct changes of the bacilli take place slowly in the expectoration; in the pure forms, that is to say, without microbial associations, the disappearance and the diminution of the bacilli are more prompt, and when this condition occurs it is invariably maintained, and it is dependent upon not only the quantity of serum injected, but the duration of the treatment. 9. The daily quantity of the expectoration constantly diminishes. 10. In the forms in which râles prevail there is a drying of the broncho-pneumonic centre and finally a disappearance of the râles. 11. The serum may be considered as a remedy for the local symptomatic processes in the extensive forms with fusion, cavities, and a high temperature, or as a curative in limited and initial forms.

Dr. Fasano thinks that this serum is a remedy that all physicians should employ, especially in the beginning, when the results are more certain, as it prevents the spread of the disease.

**Proper Names in Anatomy.**—The *Nouvelles Montpelier médical* for October 10th remarks that it has already made a protest against a mania which is tending more and more to take possession of us, that of giving to organs or to diseases the names of physicians who have made them the subjects of special study. According to the altogether up-to-date nomenclature, it says, the following will be the description of the biceps flexor cubiti given by the student of the future in the lecture room: Klefman's muscle, designated by the old anatomists under the name of brachial biceps, is situated in Casew's space. At its upper extremity it is provided with two tendons of insertion, one, Fonillini's tendon, which is attached above Trombsok's cavity, the other, Mistalievichy's tendon, at the apex of Truckmann's apophysis. At its lower extremity will be found Barackus's tendon, which is inserted into Traupmann's tuberosity. This tendon is provided with Wolberg's expansion. Klefman's muscle is innervated by Apelli's nerve, which arises from Pangemaco's trunk, etc.

**The German Medical Society of the City of New York.**—At the next meeting, on Monday evening, November 2d, Dr. F. Kammerer will show a patient on whom intestinal anastomosis has been performed on account of fecal fistula; Dr. O. G. T. Kiliani will demonstrate Kruckenberg's pendulum apparatus; and there will be a discussion on cholelithiasis.

## Lectures and Addresses.

### LECTURES ON ANGINA PECTORIS AND ALLIED STATES.

By WILLIAM OSLER, M.D.,

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

LECTURE VI.—PSEUDO-ANGINA PECTORIS (*continued*); THEORIES  
OF ANGINA.

(Concluded from page 573.)

1. THE STATE OF THE HEART MUSCLE.—During an attack the organ has been supposed to be either in spasm, or in a condition of paralysis, from imperfect blood supply or overdistention. Heberden, and many since, have regarded the heart in a paroxysm as in spasm or cramp; but Allan Burns, and after him Brodie (as quoted by Weber), urge against this view that the muscles in the condition following blocking of arteries are not in spasm, but rather the opposite; and, while not absolutely paralyzed, are, as Brodie says, in a state, approaching to it. With this the clinical features of the attack are in accord, for although it has been noted in exceptional instances that the pulse beat has not been feeble or the cardiac rhythm disturbed, the general experience is that the left ventricle is weakened and the systemic arteries imperfectly filled.

The condition of the heart muscle in the attack is probably not always the same. For example, in a patient with ten or fifteen paroxysms daily we can not suppose that any serious organic change, as anæmic necrosis, develops in each attack. In such, as Allan Burns says, "the supply of energy and expenditure do not balance each other"; "a heart with the coronary arteries cartilaginous or ossified can discharge its functions so long as its action is moderate and equal, but if the circulation is hurried, the progress of the blood along the nutrient arteries of the heart is impeded and the heart becomes fatigued." A transient paresis from insufficient supply of oxygenated blood (and possibly, as has been suggested, from a sort of auto-intoxication with the products of imperfect metabolism) explains the cardiac weakness and the tendency to syncope, but affords not the slightest clew to an explanation of the main feature of the attack—the pain. Very different to this *relative ischæmia* of the cardiac muscle must be the condition following the blocking of a large branch by a thrombus or an embolus. The resulting anæmic infarct, if at all extensive, must cause not alone great weakness of the cardiac muscle, but at the site of the lesion the smooth uniformity of the waves of contraction must be seriously interrupted. This cardiomalacia may lead to rupture of the wall of the ventricle (eleven cases in Huchard's collection of autopsies) or may cause pericarditis. While the anæmic infarct is a well-recognized lesion in fatal cases of angina pectoris, it must be remembered that a paroxysm of pain is really a rare com-

plication of this not infrequent change. It is interesting to note that the scars of infarcts have been found years after recovery from attacks of angina. Curschmann, in the discussion at the Congress of *innere Medizin*, already referred to, mentioned two cases, one a man of seventy-five years, the other a woman of sixty, both of whom, some twenty years before death, had had severe attacks of angina from which they recovered with bradycardia. There were found old fibroid changes in the myocardium with obliteration of branches of the left coronary arteries. We may say, then, that the evidence, such as it is, favors the view that the heart muscle in the attack is in a state of paresis. This, however, may not be general; it may be confined to the left ventricle or to a part of its wall; but weakness in itself offers not the slightest clew to the cause of the pain.

The view of Heberden that the heart muscle during the attack is in a state of spasm has been supported by many writers, notably by Latham. The existence of spasm of the heart during life can not be inferred from the empty and contracted condition of the left ventricle post mortem. Relative ischæmia in the territory of one coronary artery or of its main branch, still more an area of anæmic necrosis, might readily bring about conditions favoring cramp, not necessarily in the affected region (very unlikely, indeed, in an infarct), but in contiguous muscular districts, the rhythm of whose motion would be interrupted and disturbed. I do not know of cramp in the voluntary muscles produced under analogous conditions, but I may remind you of the horribly painful cramps in the legs in the exhaustion following the prolonged use of untrained muscles, and the cramps in the calves and feet in chronic arteriosclerosis. Pain, the special feature of the angina attack, is explained by the cramp theory. The most intense suffering which can be experienced is associated with muscular contractions of the tubular structures, as in intestinal, biliary, and renal colic, and in the contractions of the uterus in parturition. And observe that this agonizing pain is in parts not endowed, so far as we know, with very acute sensibility. Theoretically there is much in favor of the idea that in the most powerful muscular organ of the body irregular cramplike contractions, even if localized, might be accompanied by painful sensations, which could attain the maximum intensity present in an angina attack. But this brings us directly to a discussion of

II. THE SEAT AND CAUSE OF THE PAIN IN ANGINA.—There is one inexplicable feature which baffles all suggestion, and gives us pause in an uneasy apprehension lest we should know even less than we suppose. I refer to the extraordinary variability in the incidence of attacks in cardio-vascular lesions apparently most favorable. Why should true angina pectoris be so rare in hospital patients, and so rare in women? There must be some peculiar state of the nervous system, some un-

due susceptibility, as Sir Richard Quain says, which, in the presence of certain conditions, is really the essential factor. Like epilepsy, to which it has been compared by Trousseau, and more recently by B. W. Richardson, we know the signs and symptoms and can give a dull catalogue of predisposing causes, but of the intimate cause we know nothing, and can only formulate our knowledge in general statements, such as have been given in the lecture upon ætiology.

The seat of the pain is undoubtedly in the heart itself. The irradiation is a remarkable phenomenon to which we have no other exact counterpart in visceral disease—none, at any rate, which is so pronounced a feature. Anstie, Allen Sturge, and others have suggested the possibility of a central origin of the whole trouble; and I would here remind you of the interesting observation of Eichhorst that atrophy of the muscles of the ulnar side of the left hand may follow repeated attacks, which would suggest central changes in the spinal cord. Which set of nerves in the heart is chiefly involved, and what part the intrinsic ganglia play, we do not know. It has been suggested by Samson that the pain is due to involvement of the sympathetic fibres, the feeling of impending death to the influence of the vagi; which recalls to mind Laennec's opinion that when the pain was in the heart and lungs the vagi were affected, and, when there was simply a sense of stricture of the heart without difficulty of breathing, the grand sympathetic was involved. Four possible explanations of the pain may be mentioned:

(a) *Cramp of the Heart Muscle.*—In discussing the state of the heart during an attack I have spoken of this view, which has much in its favor, particularly in cases with anæmic infarct, but it seems scarcely applicable to all—for instance, to the cases with frequently recurring attacks, in which one can not possibly suppose infarcts to be present, though the scars, of course, persist. The analogy with painful spasm in other hollow organs, usually very insensitive, is also suggestive. That Heberden and Latham—still masters in Israel—stand sponsors for this view, and that so acute a modern observer as Rosenbach should conclude that the pain is due to “changes in the form of muscular contraction,” commend it strongly to our consideration.

(b) *Distention and Stretching of the Cardiac Walls.*—Traube held\* that the symptom-complex of angina pectoris resulted from a rapidly increasing distention of the walls of the ventricle, which, in consequence of defective nutrition, were more yielding. When, owing to increased pressure in the aortic system, this distention became excessive, the nerve elements in the heart wall became stretched and bruised, causing the pain. You will find a very careful elaboration of this theory by Lauder Brunton in the *Practitioner*, vol. xlviii. A paragraph in a lecture by T. K. Chambers also suggests

this idea: “The pain has the same tearing and paroxysmal character that you find accompanying the distention of hollow fibrous organs, usually insensitive, such as the stomach, the colon, and the bladder. The pain is of the same nature as that felt in overstrained tendons or muscles wearied out by sustained effort; it appears associated with the stretching of usually insensitive fibres, and is sometimes the most dreadful agony the body can bear, as the inventors of racks and other instruments of torture well knew.”\* Of course, this is a possible explanation, but it raises a problem insoluble as the original one—why, if extreme dilatation is a cause, angina does not occur more often. There must be surely some additional factor, or attacks would be of everyday occurrence. The relation of angeiospasm to the attacks will be discussed later.

(c) *That the Pain is in the Arteries.*—Allan Burns spoke of the pain following the tying of an artery and the application of a tourniquet. Sensory nerve endings have been demonstrated in the arterial walls, and it has been suggested frequently, in recent discussions on angina pectoris, that the main element of the attack may be *vessel-pain*, due to either angeiospasm or thrombosis. There may be—there is not always—great pain in the blocking of a large vessel, artery, or vein by a thrombus or embolus. The name *phlegmasia alba dolens* emphasizes a prominent character in the plugging of the femoral vein, and, as I have just said, the pain after ligation of the femoral or the application of the tourniquet is often very intense. Nothnagel refers also to the pain in the head in blocking of large cerebral vessels. It is not unreasonable to suppose that pain of the same nature may occur in blocking of the coronary arteries, though I do not call to mind the existence of special pain in embolism or thrombosis of arteries of the size of the coronary vessels in other organs. Moreover, as I have already said, we can not suppose that in each attack a thrombus develops. Angeiospasm is a much more likely cause of the pain, and it may be associated in some cases with blocking of a vessel. There are the analogous conditions of migraine with its vascular spasm and intense pain, and the vascular changes with pain in Raynaud's disease. Balfour has an interesting paragraph upon this question of pain in the arteries:

“That ischæmia does give rise to pain, even of the most atrocious character, is sufficiently attested by the agony that attends compression of an artery for aneurysm, especially at the moment the vessel becomes completely occluded; the pains, arising from a similar cause, that precede the appearance of gangrenous patches in a limb affected with senile gangrene; and those which precede, accompany, and follow attacks of local asphyxia (Raynaud's disease). There is every reason to suppose that the arterial spasm, which is so evidently the cause of local asphyxia, and which takes so

\* *Gesammelte Beiträge*, Bd. iii, p. 183.

\* *Lectures, chiefly Clinical*, fourth edition, pp. 315.

prominent a share in the production of an attack of angina vasomotoria, occasionally invades the heart, either as part of a general condition or, it may be, as a distinctly local affection, and that this is a very possible cause of those anginal attacks where no other seems obvious" (*The Senile Heart*).

(d) *That the Pain is a Neuralgia, either Functional or due to a Neuritis*.—This most widely held view regards angina pectoris as a form of neuralgia or neuritis affecting the nerves of the heart. Huchard mentions twenty-two modifications of this theory, which dates from the early part of the century, when, in 1808, Baumes ranked the disease as a retrosternal neuralgia (sternalgia). Laennec gave it his strong support and held that either the pneumogastric or sympathetic division of the cardiac nerves might be implicated, and with either of them the brachial plexus. Corrigan, Romberg, Bamberger, and others held the same opinion. Then in 1863 came the observations of Lancereaux on changes in the cardiac nerves and ganglia, which were confirmed by Peter and others. Huchard states (second edition, 1893) that there were only twelve observations on neuritis of the cardiac nerves, of which six were associated with disease of the coronary arteries. More recent literature, so far as I know, does not furnish additional cases, and the whole question of minute histological changes in the sympathetic nerves and ganglia in various disorders must be reviewed with the help of the new technique.

Against this theory may be urged the common observation that the cardiac nerves may be seriously implicated in aneurysm, in mediastinal tumors, in adherent pericardium, and in the exudate of acute pericarditis without causing the slightest pain.

Again, in the attack of angina, though the pain is a prominent feature, it is a part, and in a severe attack the minor part, of the paroxysm. The *angor animi* is something unlike anything met with in neuralgic affections. Moreover, the mode of onset following exertion or emotion is not a feature of neuralgia, and this view affords no solution of the sudden death which sometimes follows. In its paroxysmal character and radiation, and in its intensity, the pain is much more like that of biliary and renal colic; with the latter, indeed, I have heard a patient who had experienced both compare it.

Of course, the pain suffered in an attack of angina is a manifestation of disturbed function of the nerves. Such disturbance, when associated with pain, may be called neuralgic, but it is evident, from what has been stated, that there is something in addition, which puts the attack out of the category of ordinary painful affections of the nerves. There are many conditions about the heart in which the nerves are directly implicated with which neuralgia occurs. I have already told you that there is no constancy in this, and there may be old pericardial adhesions, fresh epicarditis with direct involvement of the superficial nerves, or there may be sclerosis

of the root of the aorta, aneurysm or tumor with pressure on the pneumogastric, without any pain whatever. But again, in all of these conditions there may be recurring attacks of pain about the heart, sometimes of great intensity, and even simulating that of true angina.

III. VASOMOTOR CHANGES IN ANGINA.—In Lecture III I mentioned the striking vasomotor phenomena of the attack—the pallor, the coldness, and the sweating—and in the last lecture I spoke of a special type of pseudo-angina in which these features dominated the scene. They play a conspicuous rôle both in the functional and organic forms. Naturally, one approaches a vasomotor problem with a good deal of caution, since it lends itself with singular aptness to theoretical vagaries and to all kinds of speculation. It is well to remember that, as Foster remarks, the vasomotor nerves are servants, not masters, in the matter of regulating the calibre of vessels and altering the blood pressure.

I have already spoken of the state of the arteries during the paroxysm, and have given a summary of my personal experience on this moot question. The general opinion is that in true angina there is an early angiospasm with great increase in the blood pressure. Sphygmographic tracings during the attack have not often been made. Lauder Brunton's observation is particularly interesting, and I show you here the tracings which he gives, taken from the radial pulse before and during an attack. It can not be doubted, I think, that in many cases an important factor is, as Mitchell Bruce expresses it, too much pressure ahead of the driving power, but this widespread peripheral spasm is probably a secondary phenomenon, excited reflexly through influences on the vasomotor centre coming from the heart itself or from other parts. Morrison, of whose paper in volume iii of the *Edinburgh Hospital Reports* I have already spoken, gives the notes of a patient with aortic insufficiency, in whom during an attack the pulse tension was low, and he thinks that even in the organic form there may be considerable variations, more especially in the cases with or without insufficiency of the aortic valve. It may be questioned, indeed, whether the tracing in Brunton's case really represents a great increase in the tension, or whether it does not mean that the left ventricle was in a condition of feebleness or dilatation, and the pulse tension extremely low. I show you here by way of contrast the tracings given by Huchard, in which, as you notice, the one in the interval between the attack with the low tension resembles very much that of Brunton's during the attack with supposed high tension.

A majority of patients with true angina have reached an age in which naturally the blood tension is increased, and in almost every instance the exciting causes of the paroxysm are those which raise the arterial pressure—mental emotion, muscular exertion, cold to the periphery, and dilatation of the stomach. You will find in Brunton's paper an admirable discussion of the impor-

tance of these factors in raising the blood pressure, and in bringing about the anginal paroxysm.

Favoring, too, this view of widespread angio-spasm is the circumstance that in certain cases of Raynaud's disease angina pectoris of a very severe type has occurred, and has even proved fatal. The most interesting case of this kind in the literature is reported by Richard Cleeman.\* A man, aged sixty-two years, had from his fiftieth year severe attacks of Raynaud's disease, chiefly in the hands, which occurred usually in the winter season. One day he had an attack of agonizing substernal pain lasting for two hours, and of such intensity that he was greatly prostrated. The pains radiated down both arms. During a period immediately preceding this he had had very pronounced attacks of local asphyxia and local syncope, chiefly in the hands. A week later he was found dead in bed.

The association of migraine with angina pectoris, particularly the vasomotor form, has been long recognized, and in two cases in my series the subjects had been great sufferers with this disease.

There are two possible explanations of the vasomotor phenomena of angina pectoris. In the first place a widespread vasomotor spasm, excited reflexly by cold, by emotion, by flatulence, etc., throws a great strain upon the left ventricle with, as Traube thought, distention, stretching, and consequent pain. Of course, in this widespread angiospasm the coronary vessels themselves may participate, and it is not at all improbable that in the hysterical and vasomotor varieties of angina the entire symptom-complex may be vasomotor. The possibility of a local (coronary) angiospasm may be admitted in the toxic cases and in organic disease of the coronary arteries. On the other hand, the widespread constrictor influence in the systemic arteries in an attack of true angina may itself be a vasomotor reflex. Hegar showed experimentally that a great increase in the general blood pressure could be excited reflexly on the injection of nitrate of silver into the peripheral artery of a rabbit. In the same way the pallor, coldness, sweating, and general vaso-constrictor influences in true angina may be excited reflexly by afferent impulses from the coronary vessels themselves.

One other matter remains for brief comment. What relation do the phenomena of spurious angina bear to those of the organic affection? Huchard insists upon the absolute separation of the organic form associated with coronary-artery disease from the various other types of cardiac pain. He says: "*Il n'y a pas plusieurs angines de poitrine: il n'y en a qu'une seule, l'angine coronarienne.*" According to him the pseudo-anginas are neuralgias of the cardiac plexus due to various causes, or a vasomotor neurosis. It must be acknowledged that the attacks of vasomotor angina and of the form seen in nervous and hysterical women have many

of the characters of a paroxysmal neurosis, resembling indeed in certain particulars migraine. Closely allied as no doubt many of the underlying conditions are, and simulating often the features of the genuine attack, I fully concur with Huchard and others who separate the functional from the organic form; and, while the former come very properly in the category of paroxysmal neuroses, the true angina presents features entirely unlike a neuralgia. The chief objections have been well and clearly put by Fagge: "But for a neuralgia to prove habitually fatal is without precedent. Moreover, angina pectoris differs from all neuroses in being generally, if not always, associated with the existence of organic lesions in the heart or in the great vessels, although it would seem that no one lesion is constantly present; this, at any rate, is true of the cases that destroy life. Thirdly, it is unlike a neuralgia to attack, as angina does by a large preponderance, more males than females—as many as ten men to one woman."

In the neurotic form the fundamental error appears to be a vasomotor instability, for which S. Solis-Cohen has suggested the name vasomotor ataxia, a term which really defines the condition, a loss of the power nicely to balance the distribution of blood in the vascular territories. In the organic form not only is the question much more complicated, but there are features quite inexplicable in the present state of our knowledge—notably the haphazard incidence in anatomical conditions apparently identical, the causation of the pain, and the relation of the blood pressure, cardiac, coronary, and systemic, to the phenomena of the attack.

Were the problems of blood pressure solved, angina pectoris would be an open book to us; but in spite of the unceasing work of the past thirty years much obscurity remains, with not a little dissonance and discord. The trained student among you who wishes to get upon a working basis should study the articles of Porter referred to in Lecture I, the important monograph of Roy and Adami,\* the *Heart Studies*† of Ewart, von Basch's works and his recent brochure on *Angiorrhagis*‡—these, with Tigerstedt§ as a sort of Baedeker, will promote his enlightenment. The less ambitious will be content with the lucid account in Stewart's *Physiology*, facile princeps among manuals on the subject.

**A Lotion for Tinea Versicolor.**—The *Province médicale* for October 3d gives the following formula for "aristocratic employment":

R Tincture of lavender.....	120 parts:
Corrosive sublimate.....	1 part:
Oil of lavender.....	4 parts:
Green soap.....	80 "

M. Apply the liquid to the affected part and let it dry; take a full bath at the end of three days. "*Tout est fini alors.*"

## Original Communications.

A CASE OF GASTROSTOMY  
PERFORMED ACCORDING TO KADER'S METHOD.

By WILLY MEYER, M. D.,

PROFESSOR OF SURGERY  
AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL;  
ATTENDING SURGEON TO THE GERMAN HOSPITAL  
AND TO THE NEW YORK SKIN AND CANCER HOSPITAL;  
CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

IN No. 28 of the *Centralblatt für Chirurgie*, July 11, 1896, Dr. Bronislaw Kader, assistant to the surgical clinic of Professor Mikulicz, of Breslau, published an interesting article, A Contribution to the Technics of Gastrostomy, in which he describes a new method of his own which is a modification of the well-known Witzel's method.\*

He states that in January, 1895, he had to establish a gastric fistula in a case of cicatricial stricture of the œsophagus and of the pylorus. The stomach was exceedingly small, and movable to such a slight extent only that most of the formerly tried methods of gastrostomy could not be made use of. Also that of Witzel—which so far had been done by Professor Mikulicz almost exclusively in cases which needed gastrostomy—could not be carried out, because a rather long incision had been made through the anterior wall of the stomach for digital exploration of the interior of the latter and of the region of the pylorus. Kader therefore modified Witzel's method, and found that the functional result in this modification was just as perfect as that of the former, while the technics—which differed rather materially from Witzel's method—presented a number of advantages, viz.: it can be done in all cases, even the most difficult ones; it can be carried out faster and in a simpler manner, and is feasible even in such cases where the character of the disease necessitated, for digital exploration of the interior of the stomach, a primary incision of the anterior gastric wall, and a longer one than we need if for gastrostomy.†

For these reasons Witzel's method has lately been substituted in the Breslau Clinic by that of Kader.

The operation is carried out in the following manner: An incision three by four inches (seven by ten centimetres) long is made, penetrating skin and fascia, and parallel with the border of the left ribs, one and a half by two fingers' width distant from the same. (In a footnote, Kader states that the simpler vertical incision might also be used. I think this should be done in every instance.) A blunt division of the left rectus muscle is made for a distance of about two and a half by three inches (six to eight centimetres). The posterior sheath of the rectus muscle and the peritoneum are incised. As will be seen, this is the way von Hacker pro-

posed for penetrating the abdominal wall.\* Now a small fold of the stomach is pulled forward in the usual way, with the help of the fingers or of the forceps, or of two slings of silk which have primarily been put through the serous and muscular coats of its wall, the wound meanwhile being held apart by blunt retractors. If the stomach is movable, the fold is, of course, drawn in front of the abdominal wall, the surrounding field being packed with aseptic gauze in order to do the following steps of the operation extraperitoneally. Then a small incision is primarily made between the two slings, and a drainage-tube of about a pencil's size introduced into the stomach for a distance of about two by two and a half inches (five by six centimetres). The few spurting arteries of the gastric wall are, as usually, ligated with fine silk (or catgut). So far, the procedure is the same as in Witzel's method. The drainage-tube is at once fastened to the side of the stomach wound by a catgut stitch (Fig. 1, a).†

FIG. 1.

Then two Lembert sutures (Fig. 1, b) are put on either side of the tube in such a way that they catch and unite a portion of the surface of the stomach of about half an inch (one centimetre) width, leaving between a groove of three fourths of an inch (two centimetres) width (see Fig. 1). The two sutures on either side are about half an inch (one by one and a half centimetre) apart. By tying these sutures ("deep occlusion-sutures"), which, of course, catch the serosa and the underlying muscularis, two longitudinal folds are formed (Fig. 1, c), which turn inward the wall of the stomach in the immediate neighborhood of the tube and thus surround the latter in the shape of a narrow funnel (Fig. 1, d). Thus the drainage-tube is situated in a canal lined by serous mem-

\* *Centralblatt für Chirurgie*, 1891, No. 32, p. 601.

† I want to state here that I fail to see any reason why this latter procedure could not be done in Witzel's operation as well.

\* *Wien. med. Wochenschr.*, 1886, Nos. 31 and 32.

† The cuts reproduce those of Kader's article.

brane which does not pass the gastric wall obliquely, but enters it in a *perpendicular, straight* way. In order to lengthen this canal, two more folds of the stomach wall are stitched on top of the first ones (Fig. 2, *c'*), in

FIG. 2.

the same manner and direction as described before, again with the help of four sutures, two on either side of the tube ("superficial occlusion sutures," Fig. 2, *b'*). The outer threads of these sutures\* are not cut short, but left long in order to have a good hold on the stomach during the further manipulations. (This I learned by personal experience to be an important point.) Now the entire area of the stomach is stitched to the edges of the peritoneal wound and that of the posterior sheath of the rectus muscle, thus rendering the operating field extraperitoneal. Then the bluntly divided rectus muscle is drawn together with the help of a few stitches, the anterior sheath of the rectus muscle sutured, and the skin closed on either side of the tube by stitches.

If wanted, feeding through the tube may be begun at once.

In establishing the fistula, one has, of course, to look out that those sutures which are put in nearest the drainage-tube are put in neither too far away nor too near to the same. The stomach wall must surround the tube in a rather gentle tension. If the stomach can not be well pulled forward into the wound, Kader advises that the deep occlusion sutures be put in primarily, and that with the help of these the stomach be drawn up against the abdominal wall in order to close off the peritoneal cavity when the incision into the stomach is made.

In a case of malignant stricture of the œsophagus very near the cardia, in which I lately performed Kader's gastrostomy myself, even this was not well feasible; I therefore had to carefully surround the field of operation, inside of the abdomen, with aseptic gauze sponges,

and to open the stomach within the abdominal cavity. As the stomach was entirely empty, no juice escaped.

Kader mentions that the folds (Fig. 1, *c*, and Fig. 2, *c'*) can be made in a perpendicular as well as in a transverse direction. The former is preferable in cases where we want to establish a permanent fistula, as in cancerous stricture of the œsophagus; the latter in benign, cicatricial ones. The canal has a greater mobility in the direction toward the cardia if the folds are put in the transverse direction. This mobility will enable us to reach the cardia easier, and thus more readily carry out retrograde dilatation, etc.

If it should have become necessary to open the stomach by a larger incision primarily, in order to explore its interior with the finger, this wound is closed by Lembert's sutures up to the spot where the tube is made to enter. Thence the operation is carried out as described above.

It is of the greatest importance to have the field of operation on the stomach well lined with peritonæum—in other words, to fix the stomach firmly to the parietal peritonæum. Kader seems to do this, according to his

FIG. 3.

diagram (Fig. 3, *c'*), by sutures where the thread passes through the posterior sheath of the rectus muscle and peritonæum on the one side, then through the stomach wall, and again through the peritonæum and the posterior sheath of the rectus on the other side. In the case in which I lately operated according to Kader's method, I did this act of the operation as I have proposed in my article on Recent Methods of Gastrostomy for Stricture of the Esophagus (published in the *American Journal of the Medical Sciences*, October, 1894)—viz., by passing a silkworm-gut suture on either end of the field of operation through the entire abdominal wall, grasping on its

\* I have marked them in the cuts, Fig. 2 and Fig. 3, with X.

way the stomach wall (Fig. 3, *e*). These sutures are tied only at the end of the operation, when the skin wound is closed with silkworm gut. They hold the stomach firmly up to the abdominal parietes. I then also stitched the fascia, plus peritonæum, around the line *ee* (Fig. 3) with a running catgut suture.

With reference to the after-treatment not much can be said. From about the third to the fifth day after the operation the catgut stitch which fastened the tube to the side of the small stomach wound (Fig. 1, *a*) will have been reabsorbed. Then the tube must be pierced by a safety pin in front of the dressings and attached to the latter (Kader), or better, I believe, as I have advised (*loc. cit.*), by slipping over the tube down to the abdominal wall a short piece of the next larger size of tubing armed with two safety pins. A piece of gauze, partially incised, is pushed underneath the pins, another one with a small centre hole on top. Both are held in place by the rubber adhesive plaster straps, as used for laparotomy, or by a square piece of muslin with a small centre hole and one or two long pieces of tape on either side, which pass around the body and are tied by the patient in front. Once a week, or oftener if desired, the tube is changed to be cleansed. It must be remembered that it should not be left out for any length of time. The fistula established according to Kader's method, as well as that of Witzel's, "closes spontaneously," or after superficial cauterization, as soon as the tube is permanently removed.

In the way just described, the operation has been carried out in Mikulicz's clinic ten times (eight times by Dr. Kader and twice by Professor Mikulicz), in five patients for cancerous and in four for cicatricial stricture of the œsophagus; in one patient the latter was compressed and impassable in consequence of a perichondritis laryngis due to specific disease. The youngest patients were five and six years old. Three times the operation was done, on account of the low condition of the patient, under local cocaine anæsthesia, after Schleich's method. All ten patients recovered without any annoying accident. The elder were allowed to get up on the second, and even on the first day after the operation. One can rely absolutely on the fixation sutures which hold the stomach firmly attached to the anterior abdominal wall.

The functional result was ideal in every case. Even when the tube was removed there was no leakage whatever, no matter how the patients turned or what position they assumed. Kader thinks that a number of causes combine to produce this satisfactory result. The serous surfaces, which are sutured together, rapidly become adherent to each other and grasp the rubber tube pretty snugly. Furthermore, the position of the inner opening of the fistula, at the tip of a compressible funnel, and the pronounced folds of the mucous membrane which run toward the entrance of this funnel (see Fig. 4) prevent regurgitation of the gastric contents. Also

the sphincterlike action of the rectus muscle, surrounding the tube on its way to the surface of the abdomen, deserves mention as an agent in rendering the fistula

FIG. 4.

water-tight. At last, it is most probable that the fibres of the muscularis of the stomach, which surround the fistula in Kader's method in a double layer, act like a sphincter. Kader emphasizes that these same causes are underlying the good functional results obtained by Witzel's method; in other words, that it is not the oblique penetration of the fistula through the gastric wall, which makes it water-tight. As frequently observed in Mikulicz's clinic, the oblique canal later assumes a straighter direction, sometimes as early as three weeks after the operation. Yet the patency of the fistula has always remained perfect.\*

On reading Kader's article I was struck by the simplicity of the procedure, and at once resolved to carry it out in a patient, Mr. J. W., aged fifty-four years, on whom I had to do gastrostomy the following day for increasing cancerous stricture of the œsophagus, from which he had been suffering since November, 1895. The operation was performed on July 21st in the presence of Dr. A. Hadden of this city, who had, together with Dr. Max Einhorn, treated the patient before. It was carried out strictly in accordance with Kader's directions, with the exceptions mentioned above—namely, that the stomach was held up to the abdominal parietes on either end of the field of operation by a silkworm-gut stitch which penetrated the entire abdominal wall, and that the field of operation was lined by peritonæum and fascia by means of a running suture. The external wound was entirely closed by stitches, layer by layer, up to the tube. The wound healed by primary union throughout and has been water-tight from the beginning. The patient was up on the fourth day after the tube had been inserted, and left the private hospital just one week after the operation. To-day, two weeks later, the fistula proves to be just as water-tight as it was on the first day after the operation; not a drop regurgitates

\* The same phenomenon was seen in one of my patients operated upon according to Witzel's method (*American Journal of the Medical Sciences, loc. cit.*).

alongside the tube or through the canal when the tube is removed. The patient is gaining in weight.\*

Since publishing my article on Recent Methods of Gastrostomy for Stricture of the Oesophagus (*loc. cit.*), where I reported fourteen cases of this operation, done by myself, in all (viz., two according to the old Fenger's, six to von Hacker's, and three to Witzel's and Ssabanejew-Frank's method each), I have done gastrostomy in nine more patients—four times according to von Hacker and five times according to Ssabanejew-Frank—twenty-three times in all. None of the last nine patients died in consequence of the operation as such. Twice the operation (von Hacker) had to be done under cocaine, as the patient's condition did not permit of general anaesthesia.

So far as the functional result of the operation is concerned, von Hacker's method has given me a uniformly good one. Only now and then the fistula commenced leaking slightly in the course of time. Then the tube had to be replaced by one of a larger size. I should still recommend von Hacker's operation as the one which can be carried out in the easiest way, taxes the patient's strength the least, and promises, if done properly, a lasting good functional result.

I should have resorted to Witzel's operation oftener—the safest and best one so far as the question of avoiding subsequent leakage is concerned—if one could, in this method, enter the abdominal cavity by bluntly dividing the left rectus muscle. I greatly like this latter procedure when establishing a gastric fistula. Wherever, during this first part of the operation, the handle of the scalpel finds a resistance in separating the muscular fibres, a transversely running blood-vessel is met with. Two clamps are applied, and the vessel divided between them. Thus the posterior sheath of this muscle and the peritonæum are rapidly reached, without any blood having been lost, and that in a most easy and convenient way, which besides proves to be of great value to the patient in the future. For these reasons I have lately combined von Hacker's and Ssabanejew-Frank's methods. But I experienced, especially in my last case of this kind, done on July 13, 1896, that the fistula leaked in the beginning, especially right after feeding. Here a comparatively short cone of the anterior wall of the stomach could be raised only, so that the small second wound had to be made below, instead of above, the border of the left ribs. In my next case I shall twist the cone for one hundred and eighty degrees—according to Gersuny's procedure on the female urethra for incontinence

of the bladder—and then, after having pulled it underneath the bluntly undermined bridge of skin, stitch the opening of the stomach to the borders of the second small wound. Hellerich, of Greifswald, has lately done this with a most satisfactory result. I should do it even if no difficulty was encountered in raising a sufficiently long cone of the anterior stomach wall.

Witzel's operation requires a more or less oblique incision and the blunt division of at least the external and internal oblique muscles. In very muscular patients, the rectus and transversalis muscles may be encountered only; in others, a layer of three muscles may have to be separated and held apart. This sometimes proves to be a rather tedious work—certainly more tedious than to divide bluntly the left rectus muscle alone—and may require the help of an additional assistant. The lining of the operating field on the stomach with peritonæum is sometimes in Witzel's operation also not a very handy procedure, especially in robust individuals.

Kader's operation, however, combines the advantages of von Hacker's and of Witzel's method in a most convenient and ingenious way, and makes the gastric fistula water-tight by entering the stomach in a direct perpendicular line, whereas Witzel tried to obtain the same result in a rather roundabout (oblique) way.

I therefore believe that Kader's method of gastrostomy for stricture of the oesophagus will be much liked by surgeons and be rapidly introduced into the surgery of the stomach everywhere.

#### REPORT OF

#### A CASE OF ACUTE ALCOHOLIC INTOXICATION IN A YOUNG CHILD,

FOLLOWED BY  
CONVULSIONS AND PARALYSIS OF CEREBRAL ORIGIN,  
AND BY MULTIPLE NEURITIS.\*

By C. A. HERTER, M.D.,

VISITING PHYSICIAN TO THE CITY (CHARITY) HOSPITAL;  
CONSULTING PHYSICIAN TO THE BABIES' HOSPITAL;  
NEUROLOGIST TO THE LIVING-IN HOSPITAL.

ACUTE alcoholic intoxication is so rare an occurrence in very young children that the condition and its

December 26, 1895

consequences have as yet been but imperfectly studied. The following instance deserves to be placed on record

\* Presented at the New York Neurological Society, April, 1896.

\*The patient was presented to the Scientific Society of German Physicians on September 25th. The functional result of the operation is perfect. It was interesting to me to watch the canal immediately after the removal of the tube. If the patient had been fed just before, a certain amount of the contents of the stomach oozed out. Meanwhile the canal in its deeper portion slowly contracted (by active contraction of the muscular layer of the gastric wall?) until the opposite walls came into contact. Then all leakage ceased, no matter whether the patient coughed or pressed or took any desired posture.

as an instructive illustration of the severe and prolonged nervous disturbances that may follow a single large dose of alcohol. Although it was disappointing not to be able to determine the precise anatomical basis of these disturbances, there is some compensation in the obser-

difficulty. The bladder is apparently full. Heart negative. Spleen and liver not enlarged. Right kidney enlarged; left kidney felt.  
14th.—The patient vomited everything in the after-

December 20, 1895.

vation of the clinical fact that such grave symptoms may be followed by what is to all appearances a complete recovery:

Charlie O'N., aged three years, admitted December 13, 1895, to Dr. Holt's service in the Babies' Hospital. Father and mother healthy. One other healthy child. Patient never nursed. Has had chicken-pox; no other contagious disease. Father of patient is a barkeeper, and the child is accustomed to small drinks of whisky. Patient perfectly well until three weeks ago, when he is said to have drunk twelve ounces at least of pure whisky one afternoon. He fell at once to the floor, cried for about two minutes, then went into a stuporous condition which lasted fourteen hours. He gave evidence of intoxication, laughing and singing, dozing at times throughout the night until eight o'clock in the morning, when he had a convulsion. Previous to the convulsion there was no paralysis. The entire face twitched, and both legs were drawn up. Convulsions recurred in five or ten minutes. Patient was given a mustard bath and castor oil. He had a movement and was apparently relieved, and went to sleep for about half a day. Was in a drowsy, stupid state the greater part of the time for a week; then the effects of the whisky seemed to wear off, and he was for a time brighter. During the next ten days he was still sleepy and irritable. There was perfect motion in the extremities during these ten days, which make seventeen days from the time the whisky was taken. Four days ago he gave evidence of pain upon urinating. From the time of intoxication until four days ago he spoke at times.

*Status Præsens, December 13, 1895.*—Both pupils respond to light. Very slight rigidity of the neck, if any. Apparently entire loss of sensation over the upper extremities. There is some apparent loss of power in the upper extremities. The feet are cold. The left leg is spastic. Sensibility is present in both lower extremities. The extensor longus pollicis is tightly contracted, lifting the great toe to nearly a right angle. The left leg is held slightly lifted from the bed. The right leg is lax and can be moved slightly. There is entire absence of patellar reflex on the right side; it is present on the left side, but diminished. Phimosis is present. Pulse, 150; temperature, 99.5°. He passes water with

noon. Pulse 160, regular, fairly strong. Respiration 32, regular. Abdomen not retracted. Liver felt just below the border of the ribs. Spleen not felt. Since admission he has lain most of the time in a condition of semi-

stupor, making no signs for anything. Last night for a few hours he was extremely irritable. Pupils are slightly dilated, and there is slight vertical nystagmus. Very slight rigidity of the neck. The feet are dropped; knee-

jerk lost. During examination he had a convulsion lasting about ten minutes. It began in the right arm and face, then it affected the right leg, the face subsiding first. He was given chloroform for the convul-

sions, and an eighth of a grain of morphine hypodermically.

15th.—Vomiting has ceased. There is constant

drowsiness. Pulse 150, regular, fairly strong. Respiration irregular. Slight rigidity of the right hand and forearm. Pupils normal in size and respond to light.

16th.—Two slight convulsions this morning of the same character as those on December 14th. Stupor not quite so deep. Marked general rigidity, a little more marked on the left side than on the right. Very slight stiffness of neck. Pupils dilated, but respond. Abdomen slightly retracted. At 4.40 p. m. a convulsion occurred, lasting five minutes. Convulsive twitching all night. Swallowing difficult.

17th.—Rigidity continues, and is most marked on the left side. Right leg completely paralyzed. Left leg and arm weak. Pupils alternately contracted and dilated. Respiration slightly irregular. Frequent slight convulsive seizures on the left side. Continues in stupor. During the night he moans occasionally as if in pain.

18th.—Rigidity continues, but is variable. Stupor less marked. Pupils dilated. The contracture of the extensor of the great toe on the left side seems permanent.

20th.—Rigidity continues, left leg still remaining flexed.

21st.—Great restlessness during early morning.

22d.—Vomited twice.

23d.—Stupor and rigidity still more pronounced. He is fed with difficulty. At 10.30 p. m. severe general convulsion occurred, especially of the left side. Extreme conjugate deviation of the eyes to the right occurred before and during the convulsion. During the past three days there has been slight but increasing flexion of the left thigh. The leg is now so extremely flexed that the heel is fixed firmly against the buttock. The right foot is extremely extended. Both hands are tightly clinched. There is some oedema of the dorsum of the left hand. There is fibrillary twitching of the tongue. From time to time there is a rapid, coarse tremor of the left side. During the night he has little or no sleep. His head is rolled almost constantly.

24th.—Tremor continues to occur. Pulse and respiration regular, but pulse very weak. Skin covered with miliaria eruption. There is conjugate deviation of the eyes to the right.

25th.—Repeated convulsions for two hours, of the same character as before. Chloroform is necessary to control them. Left side is in tremor most of the day and night.

27th.—*Tache cérébrale* pronounced.

28th.—Has considerable cough. Signs of hypostatic pneumonia behind.

During the following week the condition of the child remained practically unchanged, except that signs of consolidation of the right lower lobe became pronounced. By January 2d the convulsions began to be less frequent and the general rigidity somewhat less. The pupils at this time were very small, equal, and did not react to light. There is slight varying strabismus. The stools continued to contain considerable mucus.

January 8th.—The patient lies in a stuporous condition, the right arm paralyzed, right leg weak, left leg in extreme contracture, and the hand in typical bird-claw-hand position. Pupils medium, about equal, react to light. Slight varying strabismus. Knee-jerks not obtainable, perhaps owing to contractures.

10th.—Mental condition somewhat improved. He can be roused.

11th.—Ophthalmoscopic examination: edges of discs

somewhat hazy; vessels radiating from disc abnormally full. No distinct signs of optic neuritis.

13th.—The child is very restless, with constant rolling of the head. Has repeated slight convulsions, chiefly on the left side. There is pronounced wrist-drop. The left wrist is extremely flexed. The right foot extended. The left foot slightly flexed.

14th.—Face and neck are flushed. On the hands and knees are numerous erythematous spots of about the size of a penny, which disappeared after a few hours. There was no marked change in the condition of the child until January 23d, when the mental condition seemed much improved for a time. He recognizes his father. Contractures unchanged. Wasted muscles are tender to pressure. Vasomotor disturbances are frequently noted, especially flushing of the face. He continues to roll the head from side to side. Pupils dilated, but respond to light. Signs of complete consolidation of the right lower lobe continue.

29th.—He vomited once at 10.30 curds and mucus.

30th.—There is a moderate purulent discharge from the right ear.

February 1st.—He was very restless during the night; coughed considerably.

2d and 3d.—The condition of the patient is bad; he has lost four pounds and four ounces since he has been under observation. He is weak and looks pale. There is considerable cough. The most striking thing about the appearance of the child are the contractures and the muscular atrophy. The right arm is rigid, slightly flexed at the elbow, and the wrist is flexed and rigid. The first phalanges are well extended, the second and third flexed. There is slight return of power in the upper arm muscles. The right thigh, leg, and foot are moderately flexed, the muscles of the anterior tibial group are completely paralyzed. The left arm and forearm are very rigid and the wrist is markedly extended. The left hand is clinched and adducted. The left thigh and leg are in extreme flexion, very difficult to extend, the thigh is adducted, and the foot extremely extended. The extremities are everywhere considerably atrophied, the wasting being more pronounced on the right side, where the forearm is one fourth of an inch smaller than the left, and the thigh three fourths of an inch smaller in circumference. There is considerable atrophy of the right dorsal interossei and muscles of ball of thumb. Knee-jerks are not obtainable. Sensibility normal. No rigidity of neck; no strabismus.

6th.—Left leg and thigh give no response in any of the muscles to a strong faradaic current. In the right leg there is no response to faradism above the knee; below the knee there is no response except in the tibialis anticus and extensor longus pollicis. No response in any of the abdominal muscles to the faradaic current. On the left side the deltoid and pectoralis major contract feebly to faradism; triceps very feebly; biceps, no reaction; extensors of wrist, fair contraction; flexors of wrist, very feeble contraction. The interossei still react on the left side. In the muscles of the ball of the hand there is very feeble contraction. Muscles of the neck are normal. Contraction of the left side of the face feeble, but distinct.

On the right side, the deltoid gives fair contraction, but rather feeble.

The pectoralis major very feeble. The triceps fair; biceps good, rather slow. Extensors of wrist, good contraction. Flexors of wrist, feeble. Supinator longus, fair reaction. Interossei, good reaction. Muscles of

hand, little finger, fair reaction. Right facial nerve and muscles, fair reaction, rather feeble.

*Upper Extremities.*—All muscles react fairly well to galvanism; some muscles rather sluggishly. In every case the cathodal closure contraction is stronger than the anodal closure contraction, but in some muscles, especially on the left side, the former is very little stronger than the latter.

*Lower Extremities.*—Leg contraction everywhere obtainable with galvanism, to some extent. Cathodal closure contractions somewhat stronger than anodal closure contractions.

The child continued to lose weight until March 2d, when he weighed five pounds and twelve ounces less than on admission. Up to this time there was occasional twitching about the eyes and mouth, and occasional vomiting. In other respects considerable improvement was noticeable at this time. The contractures were less marked, and there was considerable recovery of power in the right arm, including the hand. By March 18th some power of speech had been recovered, and from this time on recovery was rapid in every direction. By April 6th he was able to use his hands freely and to move the legs about, but was still unable to stand. The contractures had disappeared, and the muscles had begun to regain their loss of volume.

*April 28th.*—The child has apparently entirely recovered. He walks well. There is no contracture anywhere, and the measurements of corresponding parts are the same on both sides. The knee-jerks are present. The muscles everywhere react promptly to a faradaic current of moderate strength, except the left quadriceps extensor, which reacts feebly. The child speaks fairly well, but stammers very much. He is said to have stammered before the onset of this illness. He is bright and fairly intelligent, and there is no evidence that his mental condition has been impaired by his sickness. The condition of the pulse, respiration, and temperature during the illness can be seen by the accompanying record.

Briefly stated, we have here a child three years and a half old who, after a large drink of whisky, went into stupor varying in depth and lasting more than two months; had a large number of convulsions, partly general and partly limited to the left side; developed right-sided paralysis, which was especially marked in the arm; extreme contractures, especially of the left side, and loss of faradaic irritability with wasting, and during the first two months had pupillary symptoms, strabismus, and repeated vomiting. During six weeks there were the signs of complete consolidation of the right lower lobe. From December 13, 1895, until February 7, 1896, there was an irregular fever which was not usually very high.

When the patient first came under the observation of the writer it was thought doubtful whether the draught of whisky could be held responsible for the symptoms. The paralysis, the stupor, the repeated convulsions, and the fever, persisting as they did, made it likely that the case was one of meningitis, implicating especially the convexity. When strabismus, vomiting, and irregular breathing became prominent, it became difficult to resist a strong suspicion that the condition was

one of tubercular meningitis. With the development of marked contractures in the extremities, with considerable muscular atrophy, loss of knee-jerk, and tenderness of the muscles to pressure (when the mental condition was such as to permit a reaction to painful sensations), it became highly probable that the child had developed a multiple neuritis of alcoholic origin. The alcoholic origin of the symptoms was made very probable, if not certain, by reliable information (not at first obtainable) as to the quantity of whisky taken.

When the symptoms of multiple neuritis became fully developed and their dependence upon alcohol became clear, it was evident that the cerebral symptoms which marked the early stage of the illness were likewise the consequence of intoxication by alcohol.

As to the nature of the anatomical changes, which we must assume to underlie the persistent cerebral symptoms, we have no information. A somewhat extended search through the modern literature of acute alcoholic poisoning has failed to discover a similar case in which the histological findings throw light upon the conditions present in our case.

Although it is necessary to use the greatest caution in transferring to man the results obtained by the experimental study of alcoholic intoxication in lower mammalian forms, the recent observations of Berkeley\* are of considerable interest in connection with the case under discussion. This observer made a careful study, by means of the Nissl method and the silver-phospho-molybdate method, of the brains of three rabbits which had been fed during three weeks with considerable, slowly increasing doses of alcohol. All the animals showed a marked loss in weight, and two of them died in convulsions. Sections from the cortical portions of the cerebra showed that the cell bodies of the nerve cells failed to give their sticho-chromic structure. They stained imperfectly; there was beginning swelling of the nucleoli and there was swelling of the branches of certain dendrons, while in other cases the dendrites were apparently atrophic.

The axons and collaterals were not implicated in the degenerative process noted in the dendrites. The cell bodies of the vascular neuroglia cells appeared increased in size and their protoplasmic extensions were thick and knotty. In the blood-vessels pronounced changes were detected. In the arteries and intermediary vessels the nuclei of the endothelial cells were everywhere swollen and in places fragmented. The alterations in the muscular protoplasm of the vascular walls were especially distinct, and indicated that the cells were undergoing a retrogressive process. In the perivascular spaces were large numbers of leucocytes in various stages of degeneration, often a number of large granular protoplasmic bodies without nucleus, and a quantity of finely granular detritus. There seems little doubt that

\* *Journal of Nervous and Mental Disease*, April, 1896.

the alterations in the nervous structures are chiefly dependent on the vascular changes which were observed.

It is not unlikely that acute alcoholic intoxication in man gives rise to alterations in the vascular and nervous elements of the cerebral cortex similar to those just referred to. Future studies will positively determine whether this is true. It is certainly unnecessary to assume the presence of a gross cerebral lesion like meningitis to explain the symptoms in our case, and a slight cortical encephalitis would probably account for both the paralytic and the irritative manifestations. The writer recalls the case of a child with pneumonia in whom there developed a persistent paralysis, chiefly unilateral in distribution. The autopsy revealed no coarse lesion; but a microscopic examination of the motor cortex showed the presence of slight vasculitis and perivascularitis.

I am indebted to Miss Wheeler, the superintendent of the hospital, for the photographs showing the contractures of the patient.

## SURGICAL CASES

### IN DOCTOR KELSEY'S CLINIC

AT THE NEW YORK POST-GRADUATE HOSPITAL

*During the Session of 1895-'96.*

By WILLIAM DUFF BULLARD, M.D.,

FIRST ASSISTANT HOUSE SURGEON.

THE cases may, perhaps, best be divided into four groups: Rectal, Abdominal, Gynecological, and Genito-urinary.

#### RECTAL CASES.

The average time in hospital of the hæmorrhoid cases operated upon by the clamp and cautery was six days and a half. This, as is well known, is Dr. Kelsey's favorite mode of treatment, although in lecturing he lays great stress upon the technics, for, simple as the operation may seem, it is capable of yielding bad results in unskilled hands; and its very simplicity may lead those to undertake it who have not had sufficient experience. The points constantly insisted upon are the amount of tissue which should be removed and the thorough way in which the cautery should be applied.

In operating for fistula no attempt is made to divide the whole length of the tract with one incision. A director is introduced into the cutaneous opening for an inch or so, when one is present, and that part of the tract is divided. After that the tract is followed by the eye and the director inserted by the sense of touch, and nothing is cut which is not plainly in view. In this way side tracts and diverticula are noted as they diverge from the main one, and are easily followed. No unnecessary tissue is sacrificed, and no branch of the main tract is overlooked. In this way only can be explained the fact that secondary operations have so sel-

dom been necessary. Several of these cases have been very severe. In two the rectum was opened for a distance of four inches, including the anus.

In one rather remarkable case occurring in a woman there was a sinus opening in each loin, both of which ran toward the sacrum. The patient had previously been operated upon in at least two of our city hospitals without success. Both tracts were traced into one common one which led into an old abscess cavity within the pelvis just under the middle of the sacrum. It was found impossible to resect enough of that bone to drain the abscess cavity without seriously interfering with the nerve supply of the pelvis, and the cavity was therefore thoroughly curetted and stuffed with gauze. The tracts were many weeks in healing, but ultimately a perfect result was obtained.

Some of the cases of prolapsus recti were remarkable for their severity, and in two an original method of treatment was adopted. Both were old cases in which all the coats of the bowel protruded, including the peritonæum, and they had been unsuccessfully operated upon several times.

The operation consisted in opening the abdomen at about the site of the incision for left inguinal colostomy, drawing the sigmoid flexure as far out of the pelvis into the wound as possible, and fixing it to the abdominal wall by three or four silk sutures, very much as is done in the ordinary operation of ventral fixation of the uterus. The abdominal incision was then closed.

One of these cases resulted in success. In another the operation was unsuccessful and the whole prolapsus was subsequently resected as follows:

After taking great care to cleanse the mucous membrane and neighboring parts by scrubbing and irrigation with bichloride solution (1 to 500), the whole extent of the prolapsus was pulled down and held out with two or three artery forceps while the bowel was plugged above with iodoform gauze. A circular incision was then made around the anterior half of the tumor, completely through the gut, just at the muco-cutaneous junction. After bleeding vessels had been secured with artery forceps the flap thus made was dissected down to the apex of the tumor. The posterior half of the tumor was next surrounded by a similar incision, and this flap also dissected off as far as the apex. Taking the two flaps thus formed in the hand and making gentle traction, the dissection was next carried upward into the apex of the tumor till a point was reached which, after amputation of the piece thus dissected loose, would allow of approximation of the cut edge remaining to the skin incision without too great traction and without redundancy of tissue. The gut was then amputated by a circular incision, the cut edge being kept from retracting with artery forceps.

After removal of the rectum there still remained a large mass of connective tissue and fat to be removed, this being especially the case in front, and in removing

this the peritonæum was freely opened. The peritonæum was closed with fine catgut. The cut end of the rectum was united to the skin incision with interrupted catgut suture. The length of rectum amputated was five inches, and the patient did well, having no further protrusion within the year.

The value of Van Buren's old method of linear cauterization was well shown in one case of very extensive disease. The patient was a young lady, otherwise strong and well, who began to have prolapsus two years before, following an attack of diarrhœa while she was at school. For some time the condition was neglected, but for the past two years she had been constantly under treatment. The tumor was as large as a man's fist and came down always upon any exertion, coughing, or sneezing. Before resorting to amputation, as in the last case, it was decided to attempt a cure by the milder method of cauterization. The iron was applied more deeply and in many more places than is usual, at least a dozen lines being burned from apex to base of the tumor, and at the base they extended entirely through the mucous membrane. Great care was given to the after-treatment. The bowels were confined for ten days, then moved with salines and enemata, with the patient in bed. After four or five such movements the patient was allowed to get up, but for a month always had her passages while lying on a commode. At the end of nine months there has been no recurrence.

#### ABDOMINAL SURGERY.

*Colostomy.*—In all cases of colostomy Dr. Kelsey has followed the rule laid down at the commencement of the session—that of completing the operation and opening the bowel at the same time, and in no case has there been any bad result. If care is exercised to close the peritonæum carefully by sutures there seems to be no additional risk in this method, and its advantages are obvious.

In one case there was annoying prolapsus of the distal end of the gut which rendered a secondary operation advisable. This consisted in reopening the abdomen, severing the gut completely across, invaginating and dropping the distal portion, and reattaching the proximal end to the abdominal wall.

*Appendicitis.*—Nine cases of appendicitis were operated upon with uniform success. In one only was the operation done between the attacks, the others being acute cases of gangrenous appendix, and most of them with large pus cavities. Two were in children, both boys, one patient (the recurrent case operated upon after the fourth attack) being ten years old, and the other an acute pus case, the patient being slightly younger. Only in the case operated upon between the attacks could the stump of the appendix be inverted, though in several of the pus cases the stump was found, ligated, and cauterized.

The following case was of special interest:

The patient, a strong young woman, had had three attacks of appendicitis within six months, and was admitted to the hospital during the third attack with all the usual symptoms. A large abscess was opened up and thoroughly cleaned out, the stump of the appendix was found and ligatured, a counter-opening was made in the loin, and thorough drainage established. A large amount of pus drained out for the first ten days, but the wounds closed completely by granulation, and the patient left the hospital apparently cured on the thirty-fifth day.

One month later the patient complained of a sudden severe pain in the region of the right lower costal cartilages which steadily increased until she was readmitted on the ninth day. An incision was made continuing the old cicatrix upward toward the diaphragm, and about six ounces of very foul pus were evacuated from a cavity just below the diaphragm. In clearing out this cavity the stump of the appendix came into view and was found in good condition.

Evidently some focus of suppuration was left after the first operation, which resulted in the second abscess; but the time required for its development and the interval of perfect health and normal temperature were noteworthy.

Too much care indeed can not be taken in breaking down and evacuating all collections of pus at the time of the operation. This was especially commented upon by Dr. Kelsey in one case in which, on the fourth day after the operation, the temperature began to rise in spite of removal of the dressings and irrigation of the wound. The patient was immediately etherized, the wound was explored with the finger, a pocket was broken down, and several ounces more of foul pus were evacuated, after which the recovery was uninterrupted.

*Intestinal Anastomosis.*—These two cases were of interest:

The first was one of cancer of the caput coli which had been treated as a fecal impaction. On opening the abdomen it was found impossible to remove the mass, which involved several coils of intestine, and as intestinal obstruction was imminent an anastomosis was made between the small bowel above and the large bowel below the growth. An oblong Murphy's button was used. On the tenth day the patient was allowed to sit up in bed, and, contrary to directions, he attempted to stand on his feet, falling back upon the bed dead. An autopsy showed perfect coaptation of the intestine and the button still in place, hanging by a shred of gangrenous tissue.

The second case was one of cancer of the pylorus, in which the button was discarded and an anastomosis made between the stomach and the ileum by Abbe's method, slightly modified by trusting to a single instead of a double row of Lambert's sutures. The patient lived only about ten days, dying of exhaustion, and the autopsy showed perfect coaptation.

Dr. Kelsey advocates the abandonment of all mechanical contrivances for securing anastomosis and trusting entirely to suturing. The time saved by the Murphy button, he believes, is very trifling, and not at all sufficient to counterbalance the risks which have been

found to attend its use. In his case of gastro-intestinal anastomosis by Abbe's method the suturing occupied about thirty minutes, being done with no attempt at haste. Although a button would have saved several minutes of this time, all the other steps of the operation would have been the same; and with the patient quietly under ether and only the parts to be sutured exposed to the air, he does not think a few minutes more or less spent in suturing likely to make any difference in the chances of the patient, except under very exceptional circumstances.

One of the most interesting cases was that of a babe of two months, with intussusception of twenty-four hours' duration, successfully relieved by laparotomy. Dr. Wiggin, in a recent study of these cases, has found only one other on record at this age. Dr. Kelsey attributes the successful result in part to the fact that no time was spent in attempts at reduction by enemata or insufflation. The diagnosis was plain when the child was brought to the hospital, the appendix being in the rectum. Nothing had been done in the way of medication or surgical treatment, and within half an hour of its appearance the child was resting quietly in its bed after the operation.

*Hernia.*—Seven operations for the radical cure of hernia were performed, all by Bassini's method. In one case suppuration occurred. Although kangaroo tendon was generally used, the operator has no great preference for it, having fully as much confidence in strong catgut prepared and thoroughly chromicized by himself. All his suture material is, by the way, sterilized by himself, and it is very unusual for him to use chromicized gut.

*Fixation of the Kidney.*—In the two cases operated upon the method was that of Dr. Edebohl's—posterior incision along the edge of the quadratus lumborum from the last rib to the iliac crest; withdrawal of the kidney, turning back of capsule, and three silkworm sutures through the reflected capsule, substance of the kidney, muscles, and skin, with closure of the incision over a deep drain of strands of silkworm gut. In one case union was by first intention, but in the other there was a deep hæmorrhage on the fourth day, which infiltrated all the surrounding tissues and could only be stopped by opening the wound and stuffing it with gauze. One of the suspensory silkworm sutures held its place, however, in spite of this, and after the wound had granulated the operation seemed to have resulted in cure.

*Biliary Calculus.*—The patient had complained for some years of pain in the region of the gall bladder and of intestinal trouble with mucous stools. The combination of symptoms had led to various conflicting diagnoses as to the nature of a tumor of about the size of a large egg projecting from beneath the ribs on the right side. The diagnosis of obstruction of the cystic duct from calculus, complicated by an ordinary intestinal catarrh, was made by Dr. Kelsey and proved by opening the abdomen over the site of the tumor. A large

calculus was removed by making an incision in the cystic duct in which it was firmly impacted. The incision was closed by fine catgut, and the abdominal wound in the usual way. Healing occurred by first intention.

#### GYNECOLOGY.

Of the twenty-nine celiotomies done for pelvic disease in women, three were for ectopic gestation.

The first case can only be accounted for by supposing the fœtus to have escaped very early from the fimbriated extremity of the tube.

The patient was thirty-three years of age, sterile for four years. Perfectly well till one week before operation, when she had sudden and severe pain in the right inguinal region without nausea or vomiting. She remained in bed three days, but on rising found she could not bear the pressure of clothing, and that there was a spot in the right groin exquisitely sensitive to touch.

Physical examination showed a painful tumor of the size of the fist in the region of the caput coli.

The diagnosis of appendicitis and the usual incision were made. The abdominal wall over the tumor was found cedematous and the peritonæum adherent to a thick-walled cyst, which was incised and emptied of about four ounces of dark-red grumous fluid and blood clots. The cyst was detached from the abdominal wall, but was so closely adherent to the appendix that the latter was amputated and the stump inverted. It was also necessary to tie off several omental adhesions and a large appendix epiploica. The sac was then removed entire and found to have no connection with either tube or ovary, which were, to gross appearances, normal. Its fœtal character was plainly shown under the microscope. The patient made a good recovery.

In a second case, in which the fœtus was still confined to the tube, the patient also did well; but in the third the sac had ruptured on the day previous to the operation while the patient was being brought to the hospital, and again while on the table being prepared for operation. The abdomen was found full of fresh and clotted blood, and a fœtus of about six months was lying loose among the intestines. The hæmorrhage was very profuse and uncontrollable until after the placenta was torn loose from its attachments in the broad ligament. The patient died in twelve hours, and an examination of the affected tube showed two ruptures. The first had been into the broad ligament where the placenta was firmly attached; the second into the peritoneal cavity through which the fœtus had escaped.

#### GENITO-URINARY CASES.

Of these, only two were of any special interest. One was a case of obscure pain in perinæum, loins, and groins, which had reduced the sufferer to a condition of invalidism, and which was dependent upon a collection of small calculi in the seminal vesicles. A transverse incision was made between the rectum and the urethra, from one tuberosity to the other, and through it the calculi were removed. The transverse incision was found

ill adapted for the purpose, its depth and funnel-shape, with the fact that the prostate closed the small end of the funnel and prevented access to the vesicles, making the operation exceedingly difficult. For such work Dr. Kelsey strongly advised in future the regular Kraske incision.

The interest in the second case was due entirely to its negative result. It was a typical one of enlarged prostate, in which castration failed to affect in any way the size of the gland or the vesical symptoms. The patient died several weeks after the operation, and the gross and microscopic appearances of the gland were carefully noted and recorded; there was absolutely no evidence of any atrophic changes. The history of the case has already been published by Dr. Kelsey, with the microscopic report of Dr. Brooks, the pathologist.

In one hundred operations the mortality was two per cent. and the failure to obtain primary union one per cent.

#### REMARKS ON SOME OF THE PRACTICAL ASPECTS OF THE LEPROSY QUESTION IN NEW YORK.\*

By PRINCE A. MORROW, M. D.

IN arranging the programme of the evening, your president has suggested that, in view of the periodical leprosy scares in this city, an illustration of the clinical features of a disease which few physicians have had an opportunity of seeing would be of peculiar interest at the present time. As is well known, the discovery of a new case of leprosy in this city is announced in flaming headlines and with the most sensational details by the public press. Columns are filled with descriptions of the horrors and dangers of the disease. The public is panicstricken with an insane fear of its dangerous spread, which is as exaggerated as it is utterly baseless. It would seem to be the duty of the profession to endeavor to allay this hysterical excitement by a careful presentation of the facts bearing upon this question from the standpoint of scientific knowledge. It is not my purpose in the remarks with which I shall preface the exhibition of these pictures to discuss the scientific aspects of leprosy, but rather to refer briefly to some of the more practical phases of the subject.

Within the past few years leprosy has assumed a new importance in professional interest. Since the seventeenth century the disease had become practically extinct in Europe. Its rediscovery by Boeck and Danielssen in Norway, some fifty years ago, was a revelation and a surprise.

To the medical profession of the present day leprosy has all the interest of a resurrected disease. With it, unfortunately, has been resurrected the traditional hor-

ror which attached to it in olden times, and with it, still more unfortunately, have been resurrected the severe and cruel measures for its repression which were formulated in the terrible edicts of the Mosaic law. For the Levitical decree under which the leper was pronounced unclean and driven forth as an outcast from the habitations of men, modern sanitary science has substituted isolation and lifelong imprisonment.

Let us glance for a moment at the attitude of the public and the profession of this city in relation to leprosy. To the popular conception, leprosy is the most loathsome of all diseases; it represents the deepest dishonor that human flesh can suffer. The term "leprosy" has crept into our literature and stands as the synonym of all that is most foul, tainted, and unclean. The leper is regarded as the bearer of a deadly contagion, to be shunned and avoided as the pest. The announcement of the presence of a leper in any assemblage or public conveyance would cause a wild stampede of all around him. He would be driven with threats of violence from any abode or lodging house at which he sought shelter or food. We see in this a survival of that superstitious dread of the disease and that spirit of intolerance which in all ages has led society to wage a relentless war against the leper.

What is the attitude of our sanitary authorities? For several years the board of health has taken official cognizance of leprosy in this city. All lepers coming within their jurisdiction are isolated on North Brother Island. At first they were quartered in a tent on the island, as far removed as possible from the other buildings; later, a cabinlike structure was erected for their confinement. At the present time they are quarantined in one of the disused buildings for contagious diseases. This commitment is virtually an imprisonment for life, unless returned by their friends to the country from which they came.

A few years ago a Chinese leper secured by the aid of friends funds sufficient to pay his passage to China. When he reached the Pacific Coast transportation was refused him by the steamship company. He was put in a box car, some food and water were thrown in, and he was shipped back to New York. The car was detached and detained at various points; it wandered through southern California and Mexico back to our borders, and finally, after indescribable suffering, the man was returned to New York. Can any one deny that every principle of common decency and humanity was violated in this case?

At the same time numbers of consumptives were transported back and forth across the continent, making use of the public conveyances and hotels without let or hindrance; and yet, any one of these consumptives was the bearer of a contagion infinitely more destructive to human life than the occupant of the box car. Why should we, from the standpoint of protection to the public health, quarantine the leper and not the consump-

\* Read before the Medical Society of the County of New York, with the exhibition of thirty lantern slides illustrative of leprosy and other diseases, Monday, October 26, 1896.

tive? Is it not a curious commentary upon the operation of our sanitary laws that thousands of tuberculous patients are permitted, within the safe precincts of their homes, in public conveyances, and on public thoroughfares, to scatter broadcast the seeds of a disease which slays its hundreds of thousands every year in this country, while public sentiment demands that every leper should be seized and incarcerated?

The mortuary statistics of this city for the last ten years show 51,718 deaths from phthisis and 9,434 deaths from other tuberculous diseases—a total of over 60,000 deaths from tuberculosis. Within the same period only two deaths are recorded from leprosy. Compared with another contagious disease, syphilis furnishes a contingent of 1,354 deaths. Of course, the murderous influence of syphilis upon the offspring is not considered in this report. From a social and socio-economic standpoint syphilis is an infinitely greater curse to a community than endemic leprosy could be, yet syphilis are permitted to propagate this disease without sanitary surveillance.

We may ask, Why this amazing inconsistency, this unjust discrimination in the application of our sanitary laws? Why is leprosy singled out from other chronic infectious diseases, infinitely more dangerous to the public health, and subjected to such harsh and severe measures for its repression? Is this course of action dictated by sound sanitary science, or prompted by considerations of public safety? Is it not rather a policy forced upon our boards of health in obedience to popular clamor?

It will be my object to show you in these pictures that from the point of view of its objective or clinical characters leprosy is not more repulsive than many other diseases of common occurrence among us—such as syphilis, cutaneous tuberculosis, cancer, sarcoma, mycosis fungoides, and other new growths of the skin. There may be seen at any time in the venereal and dermatological wards of our City Hospital examples of cutaneous disease quite as disfiguring. Cancer and sarcomatosis produce lesions more disgusting to the sight, more offensive to the nostrils, more painful, and more rapidly fatal. The mortuary statistics from which I have already quoted record 9,246 deaths in ten years from cancer, including sarcoma. Since 1886 the mortality from this source has increased over thirty-three per cent. As a matter of fact there is no infectious disease which is so long in its incubation, so mild in its initial manifestations, so prolonged in its exemption from serious accidents as leprosy. In anæsthetic cases, its entire symptomatology for five, ten, or fifteen years may be limited to a few erythematous patches and occasional neuritic pains. There is no disease of a necessarily fatal character which grants its victims so long a lease of life. Even after characteristic evidences of the disease are manifest, the patient may live in comparative health for many years with faculties unimpaired

and capacity of usefulness and work undiminished. I am speaking now of leprosy in this country under favorable conditions. I have had under my observation three patients with unmistakable signs of anæsthetic leprosy, two of twelve years' duration each, the other of seven years. In one case there has been a marked retrogression of the symptoms, with apparent cure, in the other two the symptoms have remained practically stationary. All of these are Americans who contracted the disease abroad. Now, if these individuals had been sent to North Brother Island, confined in close quarters, condemned to a life of inactivity and idleness, with no interest or occupation to distract their minds from brooding over their unfortunate condition, the result would have been vastly different.

Another practical aspect of leprosy is its contagiousness, or rather the degree of its contagiousness in this country. I say in this country advisedly, because, while I am convinced of the eminent contagiousness of leprosy in certain countries and among certain races, I believe that it is influenced largely by conditions of climate, food, and habits of life. Observation shows that lepers coming to this country almost invariably improve, for a time at least, and that the disease pursues a milder and a longer course. The very conditions which inhibit its rapid course no doubt operate in enfeebling or extinguishing its contagious activity. The soil is sterile or unfavorable, and each centre of infection dies out from the lack of conditions favorable to its development. Numerous facts might be cited to show that leprosy transplanted to this climate does not take root and flourish, but tends to die out from natural causes.

From time immemorial leprosy patients have been treated in the public hospitals of this city, and in some instances have been employed as orderlies in the wards. So far as is known no case of contagion to the other inmates of these hospitals has ever been traced to this intimate contact.

We have records of one hundred and sixty-one Norwegian lepers who have settled in the various Scandinavian colonies of our Northwestern States. There is no authentic account of a single case of leprosy originating from contact with these immigrants.

Turning now to the southern part of this country, we find that in Louisiana, where leprosy has existed since the colonial days, there has been an increase in the last twenty-five years. Dr. Blanc, in 1892, reported eighty-four cases. Dr. Dyer, in a recent letter, informs me that he has seen seventy-six cases, only five or six of whom were included in Dr. Blanc's statistics. This increase may be due to the more tropical climate, the greater susceptibility of the Creole and other mixed races, or to greater promiscuity in modes of living.

So far, however, as we can intelligently interpret the facts of experience as bearing upon the spread of leprosy in this city, the conclusion must be that such danger does not appear to be imminent.

But without reference to the imminence of this danger it must be conceded that the presence of lepers in our midst is not desirable. Leprosy in this city has been exclusively of exotic origin, and the most effective prophylactic measure would appear to be the establishment of a strict quarantine against the entry of those affected with the disease. Unfortunately, no system of quarantine can be devised sufficiently strict and searching to exclude a disease so little manifest on ordinary examination as leprosy.

The final practical point to which I would call your attention is the method of dealing with leprosy as it exists in this city. What shall be done with these unfortunates?

Our sanitary authorities, it is presumed, are disposed to act with every consideration for these people consistent with what they conceive to be the interests of the public health. The present policy of incarcerating all lepers that come under their observation is, in my opinion, to be condemned as not only cruel but a violation of the rights of the individual. If it be necessary to confine them on North Brother Island, it is necessary to continue this confinement until they die. It is, virtually, imprisonment for life. Now a system which assigns the same punishment to the unfortunate victim of disease as to a desperate criminal is opposed to humanity and justice. Moreover, this policy must fail of its purpose because of the incompleteness with which it is carried out. Any quarantine to be effective must be thorough and complete in its application. It is well known that the five lepers now at the island constitute but a small proportion of those now in this city. Merely imprisoning any stray leper that may happen to enter a dispensary or be seen wandering in the streets is but a half-way measure. If the board of health looks upon leprosy as properly coming within the regulations prescribed for small-pox, typhus fever, or other acute contagious diseases, it should, in order to be consistent, compel every physician, under penalty, to immediately report every case coming under his observation.

In an article on Leprosy some years ago (*Morrow's System*, vol. iii, Dermatology) I expressed the opinion "that in this country the compulsory segregation of lepers in lazarettos, as has been recommended by some of our health authorities, can scarcely be considered a necessary protective measure." I believe that if a leper provides himself with a separate room, bed, and board, he is practically innocuous so far as contagion is concerned. Should he require medical care, he may be safely treated in our charity hospitals, in wards specially provided, without danger to the other inmates.

This is my individual opinion. I recognize, however, that in view of the responsibility imposed upon the board of health in their capacity as guardians of the public health, the leprosy problem is a delicate and difficult one to deal with. I do not think it should be treated with careless indifference or the contempt of

ignorance. If, in the opinion of our sanitary authorities, the presence of lepers among us is a menace to the public health, of such serious character as to demand their segregation, then a home or asylum, with suitable hygienic surroundings, should be prepared for their care and maintenance by the State or national Government. Such an asylum should be arranged with special adaptation to their peculiar needs. In view of the chronicity of the disease they should not be condemned to confinement and inactivity, but should be provided with interests, means of employment, and recreation.

An intelligent discrimination should be exercised in distinguishing cases suitable for segregation.

While we know nothing definitely of the modes of infection or the conditions under which it takes place, we recognize Hansen's bacillus as the active efficient cause of leprosy. Its contagiousity will depend upon the type of the disease and its stage of development. In the pure type of anæsthetic leprosy the bacilli remain for many years localized in the nerve tissues and are not found in the cutaneous lesions. Such cases are probably exempt from all possibility of danger until at an advanced stage, when the tissues break down and liberate the bacilli. In the writer's opinion such cases bear much the same relation to the tubercular form, from the point of view of contagion, as fibroid phthisis does to acute or chronic pulmonary tuberculosis. Lepers in good circumstances, able to provide themselves with separate homes, and whose intercourse with the healthy can be restricted under sanitary surveillance, should not be subject to segregation.

Finally, if lepers are segregated, they should receive expert medical care, so that any advance in the treatment of the disease may be utilized to their advantage. The lamentable failure of our therapeutic resources is due largely to the conditions under which they have been applied. The one conviction forced upon these unfortunates when placed in a lazaretto is that they are shut up to die; the utter hopelessness thus engendered renders all treatment a failure. Says a well-known writer: "When a man affected with leprosy is taken from his home and friends, pronounced unclean, immured in a lazaretto with many loathsome fellow-sufferers, and given to understand, as is usually the case, that death is the only portal of escape open to him, the impression upon his mind is such as to counteract the effect of all remedies, and under such circumstances nothing short of a miracle could be expected to effect a cure of leprosy."

**The Buffalo Academy of Medicine.**—At the last regular meeting of the Section in Surgery, on Thursday evening, the 5th inst., the following papers were to be read: An Historical Sketch of Lithotomy, by Dr. John Parmenter; Inflammatory Diseases of the Prostate and its Appendages, by Dr. J. Henry Dowd; and The Comparative Merits of the Operations for Stone in the Male, by Dr. John B. Heath, which was to be discussed by Dr. Herman Mynter and Dr. William H. Heath.

## AN OPERATION FOR SHORTENING THE OCULAR MUSCLES IN ASTHENOPIA, ETC.

By FRANCIS VALK, M.D.,

PROFESSOR OF DISEASES OF THE EYE  
IN THE NEW YORK POST-GRADUATE SCHOOL AND HOSPITAL.

THE operation for advancement of the ocular muscles has been in use by ophthalmic surgeons for many years and has been changed and modified by many, but as it is performed at the present time it is a delicate and extensive operation in which an assistant is required; furthermore, the subsequent removal of the sutures is almost a second operation. I believe that owing to these conditions the operation is seldom performed unless it is absolutely necessary, as in cases of extreme divergent squint and paralysis of some one of the ocular muscles.

For the past two years I have successfully attempted a different method to attain the same object, provided the result desired is not too great, and think that I have succeeded in devising a method of shortening the ocular muscles that is easy to perform, that does not require an assistant or the removal of the suture, and that, moreover, produces an entirely satisfactory result.

Dr. G. C. Savage, of Nashville, Tenn., suggested in an editorial published in the *Ophthalmic Record* two years ago, the idea of shortening the straight muscles of the eye in insufficiency by taking a tuck in the muscles, using for this purpose a silk suture with two needles. I believe he was the first to publish the method of operation; but my attempts were made independent of Dr. Savage, as I was not at the time aware of his article. Still, as we have the two methods of operating, I must leave the choice to the profession, and I will describe the procedure as I now use it, showing also a new instrument that I find very useful and of great assistance to me while passing the suture. This instrument was made for me by Mr. E. B. Meyrowitz, of this city. I would also state that I was the first who used the catgut suture to take a tuck in these muscles and allowed it to be absorbed, therefore requiring no further interference with the eye in order to remove the suture. For the above-mentioned purposes I profess to be the first who has used the catgut suture in eye surgery, though I understand that Knapp has used it for some time, but for altogether different purposes—as, for example, tying the conjunctiva, etc. I have found this new method very useful in convergent squint with amblyopia, in divergent squint, in paralysis of the externi and interni, and particularly in insufficiency of the ocular muscles where the indications are to strengthen the weaker muscles, instead of as in the old method of weakening the stronger muscles by a partial or a complete tenotomy. This method of shortening has been described in the *Post-graduate* for May, 1896, and in the *Ophthalmic Record* of the same month; but to

bring it more fully to the attention of the profession, I will describe the procedure as I now perform it.

The muscle to be shortened or strengthened is first exposed by a horizontal incision in the conjunctiva and subconjunctival tissue; then, after passing two strabismus hooks beneath the muscle and forcibly separating them to the desired extent, I now pass beneath the muscle this little instrument, which I call twin strabismus hooks. This instrument consists of two arms connected by a hinge, over which hinge is placed a small spring sufficiently strong to keep the two hooks placed at the free ends of the arms well apart or separated while the suture is being applied. When in position the instrument is resting on the patient's cheek out of the operator's way. I now take a suture of No. 0 or 00 sterilized catgut that I have had put up in capsules, each containing sufficient for one operation, armed with a fine, round, half-curved needle. This needle is now passed through the tendon close to the sclera and beneath the hook, coming out above, then passing it from within outward through the upper edge of the belly of the muscle at a point as far back as we desire to shorten the muscle. It is now carried across the muscular tissue and is again passed from without inward through the lower edge and comes out below; we now pass the needle back beneath the hook through the lower part of the tendon and the needle is cut off. In passing the suture we may commence below and so simply reverse the process. Now remove the hooks and carefully tie the suture according to the desired effect.

When the suture is tied we see the small knuckle or *tuck* formed at the incision; this will slowly disappear as the suture is absorbed and the tissues firmly united. After the suture is tied I bring the edges of the opening made in the conjunctiva as nearly together as possible and then simply apply cold-water dressing. The eye is never bandaged except when the patient is going out, and, moreover, it may be used. In cases of strabismus, either convergent or divergent, I generally cut the opposing muscles by a complete tenotomy before tying the suture.

I give the records of twenty operations performed by this method, and in all the results for the relief of symptoms or for the correction of squint have been very gratifying. In only one case has there been any failure for rapid and complete healing of the muscle and conjunctiva. In squint with amblyopia this operation, combined with tenotomy of the opposing muscle, has been very successful, and I think that my experience has been sufficiently good to recommend the procedure to the profession.

The following twenty operations will illustrate the

conditions in which I think the use of the suture is indicated:

For convergent concomitant squint (1st class)	9
For convergent concomitant squint (2d class)	3
For paresis.....	1
For insufficiency of ocular muscles.....	7

Total ..... 20

In the last-mentioned cases the results have seemed to me far superior to that of a partial or a complete tenotomy, for by this method we strengthen a weak muscle instead of weakening the action of a strong one.

CASE I. *Paresis of Left Externus*.—Mr. F. A. F., aged thirty years; homonymous diplopia. May 20, 1894, put catgut suture in left externus. Result: complete relief of diplopia.

CASE II. *Weakness of Externi*.—Mrs. H. N. T., aged thirty-eight years, San José, Cal. Pain in head extending down the spine; can not use the eyes; when reading, pain much more. Refraction examined under atropine and glasses ordered; after one month's trial they do not relieve the pain in the head. Repeated examinations of muscle balance show add. 20°, abd. 0°, esophoria 6°.

January 17, 1896.—Catgut suture in left externus. Result: add. 20°, abd. 5°. Two months after the operation she reports, by letter, that she is using the eyes for reading and the pain is relieved.

CASE III.—E. W. A., aged twenty-three years. Sent to me by Dr. Carter. Headaches, frontal, extending backward. Manifest hyperopia of +.50 D. V. =  $\frac{2}{3}$  +. After repeated tests add. 16°, abd. 0°.

May 5, 1896.—Catgut suture in left externus.

Result: headaches stopped; add. 16°, abd. 4°.

In this case there was some infection of the wound.

CASE IV. *Weakness of Interni*.—Miss A. S., aged thirty years. Headaches, frontal and occipital. Refraction; compound myopic astigmatism, axes toward temples, corrected with glasses, but after four months no relief from pain. Has crossed diplopia; by prism test add. 2°, abd. 10°. From July, 1894, to July, 1895, put catgut suture in both interni and did partial tenotomy of both externi.

Result: add. 16°, abd. 8°; much better but not completely relieved.

CASE V.—Mr. C. J. F., aged thirty-two years. Has not used the eyes for working or reading during past three years; neurasthenic; complains of drawing sensation in back of head and neck. Has myopic astigmatism fully corrected by glasses, but they do not give him any relief. Crossed diplopia; by prism test 4°, and at times has double vision. Add. 12°, changing by repeated trials; abd. 10°.

November 1, 1895.—Catgut suture in right internus. Two weeks after, add. 30°, abd. 8°. Two months after operation reports by letter that he is back at work, book-keeping, and feels better than he has for several years.

CASE VI.—Miss S. J., aged twenty-five years. Is very dizzy, and has had double vision for past six months. V. =  $\frac{2}{3}$  —, Hm. 50 D., add. 3°, abd. 5°. Catgut suture in right internus. Two months after, all symptoms disappeared and add. 12°, abd. 5°. To use +.50 D. glass for reading. I saw this lady fifteen months after the operation, and on examination the lateral balance of the muscles was add. 16°, abd. 5°.

CASE VII.—Mrs. G. H., aged forty-nine years. Headaches, frontal, and has dizzy spells. V. =  $\frac{2}{3}$  — w. + 1 D., cyl. ax. 90° =  $\frac{2}{3}$  —. Add. 6°, abd. 6°. Catgut su-

ture in left internus. Three months after, reports much better. Add. 12°, abd. 6°.

*Convergent concomitant squint, first class, seven cases.*

CASE VIII.—W. G., aged twenty years. R. V. =  $\frac{2}{3}$  +; L. V. = fingers at two feet.

December, 1895.—Tenotomy of left internus. Immediate result good, but squint returned.

January, 1896.—Catgut suture in left externus. Two months after, perfect cosmetic effect; no change in vision.

CASE IX.—D. B., aged seventeen years. R. V. =  $\frac{2}{3}$ ; L. V. = fingers at ten feet. Has compound hyperopic astigmatism.

September, 1895.—Catgut suture in left externus and tenotomy of left internus. Perfect cosmetic result. Ordered + 2 D., cyl. ax. 90°.

CASE X.—S. D., aged five years; glasses for two years, correcting refraction of + 1 D. in each eye, but no improvement in squint. Operation at hospital under ether.

May, 1896.—Catgut suture in left externus and tenotomy of left internus. Perfect cosmetic result.

CASE XI.—Mrs. L. B., aged thirty-one years, Liberty, N. Y. R. V. =  $\frac{2}{3}$  w. +  $\frac{1}{15}$  C +  $\frac{1}{15}$ , cyl. ax. 180° =  $\frac{2}{3}$ . Put catgut suture in right externus with perfect cosmetic result.

CASE XII.—E. A. P., aged eight years. This boy has slight nystagmus in both eyes with the squint. R. V. =  $\frac{1}{10}$ , Hm. 2 D.; L. V. (?) ; oph. shows Hy. 6 D.

May, 1895.—Under ether and assisted by Dr. Coffin, I put catgut suture in left externus and did a complete tenotomy of left internus. Four months after, perfect cosmetic result. R. V. =  $\frac{2}{3}$ ; L. V. = fingers at 4 ft.; no nystagmus. Eight months after, same vision.

CASE XIII.—E. W., aged twenty-three years. R. V. =  $\frac{2}{3}$ , Hm. 1 D.; L. V. =  $\frac{2}{3}$  w., Hm. 3 D.; ophthalmoscope same degree of hyperopia.

March, 1895.—Catgut suture in left externus and tenotomy of both interni. Perfect cosmetic result.

CASE XIV.—F. L., aged thirteen years. This young girl had hysterical amblyopia associated with her convergent squint. Refraction, compound hyperopic astigmatism. R. V. = shadows, L. V. =  $\frac{2}{3}$ .

February, 1896.—Catgut suture in left externus while under ether. One month after, no squint and vision slowly returning. R. V. counts fingers, L. V. =  $\frac{2}{3}$ .

*Divergent concomitant squint, first class, two cases.*

CASE XV.—S. D., aged fifteen years. R. V. =  $\frac{2}{3}$ ; L. V. =  $\frac{2}{3}$  —; can fix with both eyes at near point, but at distant vision right eye turns outward.

March, 1896.—Catgut suture in right internus. Has hyperopic astigmatism, and I ordered +.50 D., cyl. ax. 90° for each eye. Result perfect.

CASE XVI.—A. C., aged fifteen years. Divergence of right eye since childhood. R. V. =  $\frac{2}{3}$  w.; L. V. =  $\frac{2}{3}$ . Refraction R. = compound myopic astigmatism; L. = Hm.

May, 1896.—Catgut suture in right internus and tenotomy of externus. Perfect cosmetic effect.

*Convergent concomitant squint, second class, three cases.*

CASE XVII.—G. F., aged seven years. Alternating squint. Hyperopia, 3 D. Atropine and glasses tried for two months; no result.

January, 1896.—Catgut suture in left externus and tenotomy of internus. Six weeks later ordered + 2 D. each eye. Result perfect.

CASE XVIII.—H. H., aged thirteen years. Right eye turns inward. R. V. =  $\frac{2}{3}$  w. — 4 D. =  $\frac{2}{3}$ ; L. V. =  $\frac{2}{3}$  w. —.50 D. =  $\frac{2}{3}$ . Under atropine R. V. =  $\frac{2}{3}$  w. — 1.50 D. =  $\frac{2}{3}$ ; L. V. =  $\frac{2}{3}$  w. — 50 C —.50, cyl. ax. 30° =  $\frac{2}{3}$ . + glasses do not correct the squint,

so I put catgut suture in right externus. Result perfect.

CASE XIX.—D. O. C., aged twenty-eight years. Convergent squint since childhood. R. V. =  $\frac{3}{80}$  w. + .50, cyl. ax.  $90^\circ$  =  $\frac{3}{80}$ ; L. V. =  $\frac{3}{80}$ , imp. w. + .50, cyl. ax.  $90^\circ$ .

August 5, 1895.—I did a complete tenotomy of right internus and next day put in catgut suture in left externus. Result perfect and with binocular vision.

In the history of my squint cases my reasons for dividing them into two classes have been published, and I note perfect cosmetic results, as I have very little confidence in the restoration of vision in an amblyopic eye, or that binocular vision should result.

In all of these cases, from both private and clinical practice, in which the suture was inserted twenty times, the results for the relief of muscular asthenopia, paresis, and squint, with or without amblyopia, have been perfect and satisfactory. In the asthenopic cases we have immediate relief and gradual improvement; in paresis the diplopia disappeared, and in squint the cosmetic effect was all that could be desired. In all the cases, except one, healing was rapid with only slight œdema of the ocular conjunctiva for a few days, and in that case there was some infection of the wound, due, no doubt, to carelessness on the part of the patient; but it finally healed with a good result. I have had Meyrowitz prepare the sterilized catgut for me and put it in small capsules, each containing a sufficient quantity for one operation; for we can only depend upon it being readily absorbed when it is perfectly sterilized.

In concomitant squint, either convergent or divergent, with amblyopia, I put in the suture and then cut the opposing muscle before the suture is tied, thereby completing the operation and placing the eye in its proper position with but one operation.

The suture can be easily applied under the anæsthetic effect of cocaine, except in young children, when I prefer to do it while they are under ether.

Fifty years ago, before Donders made his great discovery that asthenopia was due to hyperopia, the surgeons of that day frequently performed tenotomy of the lateral muscles for the relief of asthenopia, and in many cases gave relief; but Donders's discovery seems to have changed the opinions of the ophthalmic surgeons, and we now depend on glasses for relief in all cases. But modern methods of investigation have proved that while many patients are relieved by glasses, still there are those which we meet with very frequently that do not derive the expected relief from their glasses; and when we do find a decided want of balance in the power of the muscles, compared with that of the normal proportion, as stated in a paper by myself in the *Medical Record* of July 21, 1894, we are then justified in an operative procedure which will relieve the asthenopia.

In cases of muscular asthenopia I depend entirely upon the prism tests for indications in the use of the suture, for we should not deprive the eyes of their most

useful function, the guiding sensation or fusion power. At the same time bearing in mind the natural uses of the straight muscles to move the eye in different directions; and from the foregoing we can readily decide when and where the deficiency exists, and can apply the suture for its correction.

There has been so much opposition in the profession to the partial and graduated tenotomies, and still further so many failures, that some, I think, have perhaps ceased to operate; but I do not believe the same objections can hold in the case of the procedure to which I have reference. It can be applied to so many cases of insufficiency of the straight muscles without the least danger of overcorrection or of producing squint that I offer it to the profession for a fair and complete trial.

146 EAST THIRTY-SEVENTH STREET.

## Therapeutical Notes.

**The Internal Treatment of Eczema.**—Brocq and Jacquet (*Précis de dermatologie; Therapeutische Wochenschrift*, September 27, 1896) give to arthritic patients the following solution:

R Sodium benzoate..... 30 to 75 grains;  
Sodium bicarbonate..... 180 "  
Syrup..... 4,500 "

M. Four teaspoonfuls to be taken daily. For gouty patients and those affected with lithiasis, the sodium benzoate is replaced with lithium benzoate. For lymphatic and torpid individuals the following is prescribed:

R Sodium arsenite.....  $1\frac{1}{2}$  grain;  
Cherry-laurel water..... 750 grains;  
Distilled water..... 3,000 "

M. From one to four teaspoonfuls to be taken daily, before meals. Or the following may be ordered:

R Sodium arsenite.....  $\frac{3}{10}$  of a grain;  
Sodium benzoate..... 30 to 75 grains;  
Sodium bicarbonate..... 150 "  
Syrup of orange peel..... 6,000 "

M. S.: From two to three tablespoonfuls daily. Anæmic persons should take iron also. At the beginning of cutaneous congestion the following may be prescribed:

R Quinine hydrobromide.....  $\frac{1}{2}$  of a grain;  
Extract of belladonna.....  $\frac{1}{100}$  to  $\frac{1}{300}$  "  
Extract of gentian.....  $\frac{1}{2}$  "  
Glycerin..... a sufficiency.

M. To make one pill. From four to eight such pills to be taken daily.

**A Gargle for Follicular Amygdalitis.**—Levy (*Semaine medicale*, September 23, 1896; *Wiener klinische Rundschau*, October 11, 1896) recommends the following:

R Creosote..... 8 drops;  
Tincture of myrrh, } each..... 900 grains;  
Glycerin, }  
Distilled water..... 1,800 "

M.

**The Horsechestnut as a Remedy for Hæmorrhoids.**—Artault (*Revue de thérapeutique*, 1896, No. 5; *Centralblatt für innere Medizin*, October 10, 1896), acting on

the hint of the popular esteem in which the horsechestnut is held as a remedy for hemorrhoids, has used a concentrated tincture of the nut in twenty-one cases, and always with very striking results. He thinks it acts as a specific on the pain and has a direct and intense constrictive action on the veins of the pelvis. He gives ten drops of the tincture once a day, and finds that usually a few days' employment of the remedy is sufficient.

**An Application for Varicose Ulcers.**—Simonelli (*Semaine médicale; Wiener klinische Rundschau*, October 11, 1896) recommends this powder:

R Sodium chloride..... 10 parts;  
Menthol..... 1 part.

M. After cleansing of the ulcer this is to be dusted on. Under this treatment even perfectly atonic ulcers soon begin to granulate healthily, and then they may be treated with cauterization, skin-grafting, etc.

**A Lotion for the Itching of Urticaria.**—The *Province médicale* for October 3d gives this formula as "for the itch":

R Distilled water..... 450 parts;  
Cherry-laurel water..... 50 "  
Chloral (hydrate?)..... 5 "  
Cocaine hydrochloride..... 3 "

M.

**Ichthyol in the Treatment of Gonorrhœa.**—Canova (*Thèse de Paris*, 1895; *Centralblatt für Gynäkologie*, October 10, 1896) recommends a one- or two-per-cent. solution of ichthyol as a urethral injection. He says it is painless and very efficient; in a few cases it has cured the disease in so short a time as six days.

**The Incompatibility of Antipyrine and Calomel.**—Dr. H. Werner (*Pharmaceutische Zeitung*, June 10, 1896; *Wiener klinische Rundschau*, October 11, 1896) gives a caution against the simultaneous use of these two drugs. Their reaction results, he says, in the formation of a dangerous amount of corrosive sublimate even when ordinary medicinal doses are given.

**Arsenic in the Treatment of Lupus Erythematosus.**—At the Sixty-eighth Congress of German Naturalists and Physicians, held in September (*Deutsche Medizinische Zeitung*, October 5, 1896), Dr. Joseph Schütz, of Frankfurt on the Main, spoke of the unsatisfactory results of prevailing methods of treating this disease, and particularly of the positive harm done with highly irritating applications employed for too long a time. He had found that arsenic in very weak solutions had a favorable influence on the disease; Fowler's solution, diluted with from four to six times its weight of water and painted on the affected area twice a day, caused within six days swelling and slight painfulness of the part, but without any exudation of serum; this condition subsided in eight days more under the use of mild pastes. The arsenic spared the healthy tissue. By this treatment he had cured nine cases. Healing had taken place without the formation of scars.

**Apenta Water to Correct the Unpleasant Effects of Morphine.**—In an article entitled Notes on Apenta and Some Other Bitter Waters (*British Medical Journal*, September 26, 1896), Dr. Julius Althaus remarks that it is useful to know that in cases where we are obliged to give morphine Apenta water has an excellent effect in neutralizing its prejudicial action on the hepatic functions, acting much better than mercury or podophyllin.

THE

## NEW YORK MEDICAL JOURNAL, A Weekly Review of Medicine.

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 7, 1896.

### MUSHROOM POISONING.

ONE of our Paris contemporaries, the *Progrès médical*, sounds a timely note of warning against trusting to the "instinct" of persons who, having no scientific knowledge of the subject, profess to be able to distinguish unerringly between the edible and the poisonous fungi. It seems that an unusually large number of cases of toadstool poisoning occurred in various parts of France during the month of September, and among them, and singularly emphasizing the *Progrès's* caution, was the death of a man and his wife who for more than fifty years had dealt in mushrooms. Three cats that had eaten these persons' dejecta died also.

Our contemporary speculates as to whether or not the storms that are so apt to occur in the early part of September make the poisonous fungi particularly dangerous at that time. It remarks that the plants of tropical regions have an activity of secretion quite different from that possessed by the same plants growing in temperate districts. However that may be, says the French journal, the ordinary tests to distinguish the edible from the poisonous fungi, such as the odor, the taste, and observing whether or not they blacken a silver spoon in the cooking, are not to be trusted; it is only the botanical characteristics that can be relied on. Besides, the writer continues, it is not true that poisonous species become harmless on boiling, expression of the juice, or maceration. In the public markets, especially in Paris, only the innocent species, those that are the most commonly cultivated, are to be found, but many amateur cultivators of fungi are given to raising species that not all of them are able to distinguish from various poisonous species of *Amanita*.

The frequency with which fatal cases of mushroom poisoning are reported at the time of the year mentioned, that of the early rains and the first mushrooms, the article goes on to say, shows how cautious one should be in the tentative consumption of fungi that grow wild in the meadows and woods; persons who imprudently trust themselves to select edible mushrooms, relying on their instinct in the absence of scientific information, expose themselves to terrible dangers.

The *Progrès* tells of an excellent plan that occurred

to a pharmacist in one of the regions in which the accidents in question had happened. He put specimens of the poisonous mushrooms of the neighborhood into preserve jars and kept them on view in his show-window, so that persons passing his shop could learn a most instructive object lesson if they were willing to stop for an instant. This pharmacist must be a most benevolent man, but not every community can rely on having his like. In this country, fortunately, the government publications give ample means of distinguishing the edible from the poisonous among fungi, and mushrooms unexcelled in flavor and nutritive value grow in the United States.

#### THE ARMY MEDICAL SCHOOL.

THE *Report of the Surgeon-General of the Army* for the year ending June 30, 1896, contains an interesting report by Assistant Surgeon-General Alden, the president of the Army Medical School. It seems that the last formal session began in November, 1895, and closed in the following March. Up to the beginning of that session, the school had not been formally open since February, 1894, owing to the fact that during that interval no new medical officers were appointed, but from time to time instruction was given to some of the older officers of the medical corps in the chemical and pathological laboratories.

The main courses of instruction given, says Colonel Alden, were in the duties of medical officers, in military surgery, in military medicine, in military hygiene, in sanitary chemistry, in clinical and sanitary microscopy, in hospital-corps drill, and in first aid to the injured. The members of the faculty are stated to have taken advantage of experience acquired at the former session to improve their courses, especially in the direction of making them more practical. Particular mention is made of the value of the course in operative surgery on the cadaver. In regard to his own branch, that of the duties of medical officers, President Alden says that it has been made as practical as possible without a direct connection of the school with a military post or military hospital.

In addition to the instruction given by the regular faculty of the school, auxiliary courses were given as follows: Five lectures on military law, by Lieutenant-Colonel Davis, deputy judge-advocate general of the army and professor of military law at West Point; four clinical lectures on mental diseases at the Government Hospital for the Insane, under the direction of the superintendent, Dr. W. W. Godding; lectures on the Army Medical Library, by Dr. Robert Fletcher,

principal assistant librarian of the Surgeon-General's Office; lectures and laboratory demonstrations on parasites in man, by Professor C. W. Stiles, of the Department of Agriculture; and instruction in horsemanship, by Lieutenant H. A. White, of the Sixth Cavalry, under the direction of Colonel Gordon.

President Alden says that the faculty has watched with interest the career of the officers who passed out from the school at the close of its first session, and a gratifying showing has been the result. He finds that the relative standing of members of the class, as determined by examination at the end of the school course, is not the same as that attained by them on their examination for admission into the medical corps. It is the standing last mentioned that determines their rank, but the recommendation made in a previous report is repeated, in order to establish an incentive to the student officer—that his final rank in the army be made to depend on a combination of the marks attained on his entrance into the service and those earned in the school work.

#### MINOR PARAGRAPHS.

##### LAXITY OF THE JOINTS.

At a recent meeting of the Vienna Medical Club (*Therapeutische Wochenschrift*, October 18, 1896) Dr. Frey showed a boy, three years old, who, in addition to extreme laxity of the finger joints, had a forward luxation of the hand which could readily be converted into a backward dislocation. Moreover, the elbow joints were abnormally broad, and the radius could be displaced in various directions.

##### THE COMPARATIVE SAFETY OF TRIONAL AS A HYPNOTIC.

BEYER (*Deutsche medicinische Wochenschrift*, 1896, No. 1; *Fortschritte der Medicin*, October 15, 1896) remarks that, in spite of the widespread employment of trional, only six cases of poisoning with that drug are known. One was an instance of acute poisoning; more than one hundred and five grains was taken at a single dose, with suicidal intent, but the person survived. Of the cases of chronic trional poisoning, only one, Hecker's, can be accepted as purely the result of taking the medicine. The patient recovered after discontinuing the use of the trional, which he had taken in daily amounts of twenty-two grains for thirty-six consecutive days. It may therefore be said that trional is one of the best hypnotics, if not quite the best, for unpleasant effects are readily avoided if it is used properly.

##### ITEMS.

The New York City Civil Service Commission will hold the following examinations at its office in the New Criminal Court Building at 10 A. M. on the dates named. Applicants must be over eighteen years of age, citizens of the United States, and residents of the State of New York. Applications may be obtained from S. William Briscoe, secretary, New Criminal Court Building, New York city.

**November 12th.**—Lay sanitary inspector, Health Department. Candidates will be examined on sanitation, etc. Salary, \$1,200 per annum.

**November 13th.**—General inspector, Department of Public Charities. Candidates must have had executive experience in hospital management and organization. Salary, \$3,000 per annum.

**November 24th.**—Bacteriologist. Candidates must hold the degree of M. D. Knowledge of bacteriology required. Salary, \$1,200 per annum.

**November 24th.**—Assistant bacteriologist, Health Department. Knowledge of general bacteriology required. Salary, \$600 per annum. Candidates required to hold the degree of M. D.

Medical chief of staff, Department of Public Charities. Candidates must hold the degree of M. D. and have had experience in hospital organization and management. Salary, \$3,000. The date of this examination will be announced at a future time.

**"Infectious Diseases" in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 3, 1896:

DISEASES.	Week ending Oct. 27.		Week ending Nov. 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	26	7	27	6
Scarlet fever.....	80	5	83	5
Cerebro-spinal meningitis....	0	0	0	0
Measles.....	61	2	41	2
Diphtheria.....	175	21	194	20
Tuberculosis.....	174	101	99	105

**The Rush Monument Fund.**—The secretary of the Rush Monument Committee, Dr. George H. Rohé, reports on October 31st that the following subscriptions to the fund have been received since he last reported:

April 17th, Dr. J. W. Hoff, Pomeroy, O.....	\$5.00
Dr. T. J. Acker, Croton-on-Hudson, N. Y.....	5.00
" 30th, Peoria City Medical Society (through Dr. O. B. Will), Peoria, Ill.....	25.00
Dr. D. W. Cathell, Baltimore.....	1.00
Dr. W. T. Cathell, Baltimore.....	1.00
May 9th, Dr. J. P. Getter and others, Mifflin Co., Pa.....	3.00
" 21st, Dr. E. H. Bishop, Towson, Md.....	1.00
June 10th, Dr. C. B. Burr, Flint, Mich.....	10.00
" 29th, Dr. W. H. Hardin, Anderson C. H., S. C.....	1.00
Herkimer Co. Med. Soc. (through Dr. G. Graves, Herkimer, N. Y.).....	25.00
Sept. 30th, Dr. J. W. Grosvenor, Buffalo, N. Y.....	1.00
Interest to date.....	81.00
Before reported.....	159.00
Total, \$3,856.39	3,727.39

**The New York Academy of Medicine.**—The programme for the last general meeting, on Thursday evening, November 5th, included the Wesley Carpenter Lecture, on The *Ætiology and Classification of Infectious Diseases*, by Surgeon-General George M. Sternberg, of the army; and a paper on The Physical and Schott Treatment of Chronic Heart Disease, by Dr. H. Newton Heineman.

At the next meeting of the Section in General Surgery, on Monday evening, November 9th, patients will be shown, and Dr. Edward M. Foote will read a paper on Formalin in the Treatment of Septic Wounds.

At the next meeting of the Section in Genito-urinary Surgery, on Tuesday evening, November 10th, patients, new instruments, and specimens will be shown, and Dr. John A. Wyeth will read a paper on The Treatment of Strictures of the Male Urethra.

At the next meeting of the Section in Pædiatrics, on Thursday evening, November 12th, a patient will be pre-

sented, and papers will be read as follows: An Epidemic of Glandular Fever, by Dr. J. P. West, of Belaire, Ohio; and The Mode of Examining Sick Children, by Dr. J. Lewis Smith.

**The Sick Nurses' Fund.**—On Thursday, November 19th, from three to six o'clock in the afternoon and from eight to ten in the evening, the nurses of the New York Hospital will conduct a tea and sale in the administration building, No. 8 West Sixteenth Street, for the benefit of the sick nurses' fund.

**The Bender Hygienic Laboratory.**—The dedication of the Bender Hygienic Laboratory, in Albany, took place on Tuesday evening, October 27th. The order of exercises included a history of the building, by Dr. George E. Gorham, and an address by Dr. A. Jacobi, of New York.

#### Society Meetings for the Coming Week:

**MONDAY, November 9th:** New York Academy of Medicine (Section in General Surgery); New York Academy of Sciences (Section in Chemistry and Technology); New York Medico-historical Society (private); New York Ophthalmological Society (private); Lenox Medical and Surgical Society, New York (private); Microscopical Club of the Buffalo Society of Natural Sciences; Gynecological Society of Boston; Maine Academy of Medicine (Portland); Burlington, Vermont, Medical and Surgical Club (annual); Norwalk, Connecticut, Medical Society (private).

**TUESDAY, November 10th:** New York Academy of Medicine (Section in Genito-urinary Surgery); New York Medical Union (private); Buffalo Academy of Medicine (Section in Medicine); Kings County, N. Y., Medical Association; Medical Society of the County of Rensselaer, N. Y.; Newark (private) and Trenton, N. J., Medical Associations; Camden, N. J., County Medical Society (semiannual—Camden); Clinical Society of the Elizabeth, N. J., General Hospital and Dispensary; Northwestern Medical Society of Philadelphia; Practitioners' Club, Richmond, Kentucky; Richmond, Virginia, Academy of Medicine and Surgery; Norfolk, Massachusetts, District Medical Society (Hyde Park).

**WEDNESDAY, November 11th:** New York Pathological Society; New York Surgical Society; American Microscopical Society of the City of New York; Society of Alumni of the City Hospital, New York; Medical Societies of the Counties of Albany and Allegany (quarterly), N. Y.; Pittsfield, Massachusetts, Medical Association (private); Philadelphia County Medical Society.

**THURSDAY, November 12th:** Society of Medical Jurisprudence and State Medicine, New York; Brooklyn Pathological Society; New York Physicians' Mutual Aid Association (annual); Medical Society of the County of Cayuga, N. Y.; South Boston, Massachusetts, Medical Club (private—annual); Pathological Society of Philadelphia.

**FRIDAY, November 13th:** Yorkville Medical Association, New York (private); Brooklyn Dermatological and Genito-urinary Society (private); German Medical Society of Brooklyn; St. Louis Academy of Medical and Surgical Sciences; Cleveland Medical Society; Medical Society of the Town of Sagerties, N. Y.

**SATURDAY, November 14th:** Obstetrical Society of Boston (private); St. Louis Medical Society.

#### Births, Marriages, and Deaths.

##### Married.

**EATON—POTTER.**—In Lancaster, N. Y., on Wednesday, October 28th, Mr. Lewis Eaton and Miss Fanny Maud Potter, daughter of Dr. Samuel Potter.

**HITZ—WINKLER.**—In Milwaukee, on Wednesday, October 28th, Dr. Henry B. Hitz and Miss Louise Dorothea Winkler.

MURPHY—MAMBERT.—In Troy, N. Y., on Thursday, October 29th, Dr. Parker H. Murphy, of Albany, and Miss Estella M. Mambert.

NEFF—PHILLIPS.—In Amsterdam, N. Y., on Wednesday, October 28th, Dr. Daniel D. Neff and Miss Abigail Phillips.

PAYNE—WRIGHT.—In New York, on Wednesday, October 28th, Mr. Halbert Edwin Payne and Miss Grace Grosvenor Wright, daughter of Dr. J. Williston Wright.

TRAYER—BROWN.—In Providence, R. I., on Wednesday, October 28th, Dr. A. W. A. Trayer and Miss Marion Augusta Brown.

WATKINS—MOSS.—In Lake Charles, Louisiana, on Wednesday, October 28th, Dr. T. H. Watkins, formerly of Jackson, Mississippi, and Miss Bertha S. Moss, daughter of Dr. A. H. Moss.

Died.

COLEMAN.—In Granville Ferry, Nova Scotia, on Saturday, September 5th, Dr. James Anderson Coleman.

HULL.—In Providence, Rhode Island, on Monday, October 26th, Amelia E. Hull, wife of Dr. James C. Hull.

SMITH.—In Williamstown, Massachusetts, on Saturday, October 24th, Dr. Andrew M. Smith.

## Letters to the Editor.

### AN UNWARRANTABLE USE OF A NAME.

THE PAVEMENT, NOTTINGHAM, ENGLAND, September 5, 1896.

To the Editor of the New York Medical Journal:

SIR: There has this week been sent to medical men in England a pamphlet advertising an American nostrum called sanmetto. In this pamphlet is what purports to be a testimonial from me.

This is an absolute forgery, as I have never used or in any way recommended the drug.

I shall be obliged if you will kindly publish this disclaimer and draw attention to this latest and most injurious development of business "enterprise."

I inclose a copy of the "testimonial" and have to add that I am taking legal advice as to how to stop and punish the fraud.

W. B. RANSOM, M. D.

## Book Notices.

*A Text-book of Histology, Descriptive and Practical. For the Use of Students.* By ARTHUR CLARKSON, M. B., C. M. Edin., formerly Demonstrator of Physiology in the Owens College, Manchester, etc. With One Hundred and Seventy-four Original Colored Illustrations. Philadelphia: W. B. Saunders, 1896. Pp. xx-554. [Price, \$6.]

THE object of this work, as stated in the preface and evident in the contents of the volume, is to furnish students of histology with both the descriptive and practical parts of the science of microscopical anatomy. The bulk of the volume is therefore about equally divided between descriptions of the histology of the tissues and viscera, and colored plates illustrating these structures. It scarcely need be said that an undertaking of such magnitude in a single volume can hardly fail to fall short of complete success. An examination of the work in detail shows that the wants of students only

have been considered in the compilation of material, and the failure to meet the wants of histologists can not be urged against this or any other of the many text-books written for the class room.

Two preliminary chapters are devoted to the subjects of hardening, imbedding, sectioning, and staining tissues for microscopical examination. Here are given the usual methods employed in this work, among which may be noticed some peculiar to English laboratories, for instance, the practice of imbedding in gum. Formalin is not mentioned as a fixing agent or as an adjunct to the use of the freezing microtome.

In describing endothelium as a variety of epithelium the author may be regarded by many as fully abreast with, and by some as rather ahead of, conservative authorities. In the chapter on the histology of the blood is successfully gathered, in small compass, a considerable portion of the subject of the blood of vertebrates, but the descriptions of technics are insufficient to enable the student to make satisfactory preparations of the blood for microscopical examination. Ehrlich's classification of leucocytes is in America rather preferred to that of Schultze.

The description of the histology of striated voluntary muscle fibre is most excellent, and an agreeable departure from the usual elementary treatment of the subject required by the scope of the work is to be found in the study of the histological changes in contracting muscle fibre as originally described by Professor Hayscraft.

Throughout the descriptions of the viscera the requirements of students have been carefully considered, and almost without exception have been well met. The illustrations representing the larger blood-vessels and that of the tonsil are, however, unsatisfactory, and not in accord with the general excellence of this feature of the work.

Compared with some more complete text-books on histology, such as the histological descriptions of *Quain's Anatomy*, this volume seems almost like an attempt to popularize the subject. Considered in its proper field it will be seen at once that the volume in the hands of students will greatly aid in the comprehension of a subject which in most instances is found rather difficult. For this purpose the work must be considered a valuable addition to the list of available text-books, and is to be highly recommended.

*A Treatise on Appendicitis.* By JOHN B. DEEVER, M. D., Surgeon to the German Hospital, Philadelphia. Containing Thirty-two Full-page Plates and other Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1896. Pp. xv-17 to 168. [Price, \$3.50.]

No subject in surgery has undergone more thorough and careful examination in the past three years than appendicitis. The frequency with which cases are seen and the numbers of them which are reported justify the inquiries of the laity as to whether it is a disease produced by the habits of modern civilization or whether it was unrecognized in previous years. The present work, as well as those of Morris and Fowler, fail to answer this question satisfactorily, but they show us something far more important—viz., that our surgeons know more about the disease, its varieties, and its management than was dreamed of a decade ago.

The author has gone over the history, anatomy, ætiology, pathology, symptomatology, diagnosis, prog-

nosis, treatment, complications, and sequelæ of the disease. He holds the anatomical structure of the organ to be one of the chief predisposing causes of the disease, and lays great stress upon the fact that it has no anastomotic blood supply to maintain vitality when its one artery is interfered with by torsion or otherwise. The length and attachment of the meso-appendix are also of importance, as the shorter the mesentery the greater will be the curvature of the appendix, and consequently it will be less easily emptied of its contents. The writer does not think constipation, diarrhœa, or foreign bodies have any great causative influence in the majority of cases. The frequency of the disease is in inverse proportion to the age after thirty years, and men are much more liable to it than women, on account of the better blood supply to the organ in the latter. He points out in support of this theory the observation of Clado that there is a fold of peritonæum passing from the right ovary to the appendix which carries a small artery and thus supplies anastomotic circulation in females.

As to the exciting causes, he lays the greatest stress upon the invasion of micro-organisms, of which the appendix is always the seat. As to fecal stones, it is difficult to follow the author's logic when he maintains that they are the result of the inflammation and not the cause. The method of their formation in concentric layers, just as with stone in the bladder, presupposes, of course, a nidus or central body upon which the concretions may form. This may be a foreign body, a bit of inspissated mucus, or, for the sake of argument, a product of inflammation. As a matter of fact, however, it would take months if not years for a stone of any size to form by this process, and it seems improbable that the inflammation, which generally lights up with such suddenness, should have been present through all this period. At least, it seems to us much more probable that the "coprolith" by its gradual growth, distention of and pressure upon the walls of the appendix, should be the cause of the inflammation, rather than the reverse.

The division of the stages of appendicitis into endo-appendicitis, parietal appendicitis, peri-appendicitis, and para-appendicitis is no doubt scientific, but of no practical value, as there are no symptomatic dividing lines between them, and we question whether such minute subdivisions are not more confusing than helpful.

The gist of the chapter on treatment is found in the following two sentences: "Appendicitis is a surgical affection, and should be treated as such." "There is but one sure road to recovery, viz., early operation." This is the almost universal opinion of surgeons, and it remains for the practitioner to learn how to operate, what are the sequelæ he is apt to meet with, and how to manage them. These questions are ably treated of in the last chapter of this interesting book, and we can therefore recommend it as a full, safe, and reliable guide to all our readers.

#### *On Germinal Selection as a Source of Definite Variation.*

By AUGUST WEISMANN. Chicago: The Open Court Publishing Company, 1896. Pp. xii-61. [The Religion of Science Library.]

THIS very entertaining essay by the professor of zoology at the University of Freiburg is offered in further answer to the Spencerian tenet that the adaptations necessary for animal existence are produced by acci-

dental variations, and not by any force of utility or selection. The essay is therefore an attempt to free this department of natural science from the teleological principles inherent in materialism.

Without attempting to review the argument in detail, it may be stated that the writer, while admitting the existence and importance of accidental variations, holds to the Darwinian principle of *selection* in the production of species, and specially emphasizes the action of this principle on the *germ-plasm*. The article is an interesting and valuable addition to the author's work entitled *Germ-plasm*. A complete index greatly facilitates access to the numerous references of the text. The translation, by T. J. McCormack, is, in point of phraseology, very commendable.

#### BOOKS, ETC., RECEIVED.

*System of Diseases of the Eye.* By American, British, Dutch, French, German, and Spanish Authors. Edited by William F. Norris, A. M., M. D., and Charles A. Oliver, A. M., M. D., of Philadelphia. Volume I. Embryology, Anatomy, and Physiology of the Eye. With Twenty-three Full-page Plates and Three Hundred and Sixty-two Text Illustrations. Philadelphia: J. B. Lippincott Company, 1896. Pp. xvii-7 to 670. [Price, \$5.]

*The Practice of Medicine.* By Horatio C. Wood, A. M., M. D., LL. D. Yale, Professor of Therapeutics and Clinical Professor of Nervous Diseases in the University of Pennsylvania, etc., and Reginald H. Fitz, A. M., M. D., Hersey Professor of the Theory and Practice of Physics in Harvard University, etc. Philadelphia: J. B. Lippincott Company, 1896. Pp. x-1088.

*A Text-book of Materia Medica, Therapeutics, and Pharmacology.* By George Frank Butler, Ph. G., M. D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Chicago, etc. Philadelphia: W. B. Saunders, 1896. Pp. 11 to 858. [Price, \$4.]

*A Treatise on Obstetrics for Students and Practitioners.* By Edward P. Davis, A. M., M. D., Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic, etc. Illustrated with Two Hundred and Seventeen Engravings and Thirty Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xi-17 to 553. [Price, \$5.]

*The Diary of a Resurrectionist. 1811-1812.* To which are added an Account of the Resurrection Men in London and a Short History of the Passing of the Anatomy Act. By James Blake Bailey, B. A., Librarian of the Royal College of Surgeons of England. London: Swan, Sonnenschein & Co., Lim., 1896. Pp. xii-13 to 184.

*Some Studies of the Blood in Thyroid Feeding in Insanity.* By Middleton L. Perry, M. D. [Reprinted from the *Medical Record*.]

#### Miscellany.

**The Sepsis of the New-Born.**—The *Journal of the American Medical Association* for October 17th publishes the following account of a case which was reported by Dr. Henry E. Tuley at the recent meeting

of the American Medical Association. The author records it not only because of its rarity, but because of the interest attached to the case in connection with its etiology: The child was born of a healthy primiparous mother after a normal though rather tedious labor which had to be terminated by forceps. The child was a male weighing about seven pounds; it cried well and was quite vigorous.

The mother had no vaginal discharge before labor, but a vaginal douche of a 1-to-2,000 solution of bichloride of mercury was given upon the advent of the first pain; none were given afterward. Her puerperium was perfectly normal.

As soon as the head was born the eyes were wiped and the face was washed, the first bath being given some hours later. The cord was tied with a piece of silk from a skin which had been used the day before in an ovariectomy, and some of the same was used the next day in an abdominal operation, without further preparation. After the first bath the cord was dressed with talcum powder and wrapped in absorbent cotton.

During the first three days nothing abnormal was noted with the child; it had a normal temperature, nursed well, though apparently not satisfied, slept well, and had normal movements. On the fourth day a temperature was reported of 101.4° F. in the morning at six o'clock, and it had risen to 104° by noon. Dr. Tuley was asked to see the case at this time by the attending physician, Dr. L. S. McMurtry. It was decided that the temperature was a starvation one and that artificial feeding was indicated; it was accordingly put upon cow's milk, well diluted, to supplement each nursing, temporarily, as the breasts were at this time beginning to secrete. This reduced the temperature in five hours to 100.6°, and the next day the temperature was normal and the child seemed as well as usual. The cord dropped off the next day, the fifth, leaving a moist base, which was treated aseptically and dressed with talcum powder. The next day the temperature rose to 102.4° and the child was reported as listless and slow about nursing. Dr. Tuley was asked to see the child again at this time, and on close examination he found a retracted umbilicus, which, on depressing the edges, was found to contain about twenty drops of pus; this when wiped away showed the base or stump of the cord to be fungous in character. The child did not stand manipulation of the parts well, pain being caused when they were cleansed, and there was noted slight distention of the abdomen. After thorough cleansing of the navel with a bichloride-of-mercury solution, the fungous navel was touched with a twenty-grain-to-the-ounce solution of nitrate of silver and a powdered boric-acid dressing applied. This dressing was renewed twice daily and the silver solution used as before.

From this time to the child's death, three days later, the temperature rose continuously and steadily from an initial one of 102.4° to 107° a few hours before its death. Baths would reduce this a degree or so, but it would rise again in a few hours. It refused to nurse and was with difficulty fed breast milk, which had been pressed out for feeding with a medicine dropper. The day before its death it had passed very little urine and had several movements, which were composed almost entirely of mucus. The bowels were irrigated with plain water, which regulated this condition to a degree and also increased the amount of urine voided. On the day it died the skin was very hot and dry, and it was put into a hot-air bath, but this caused so much prostration that it was

removed, and stimulation kept up to the time of its death. A few hours before this occurred its hands and feet were noticed to become purplish and perfectly cold, and this condition had extended to the wrists and nearly to the knees before death. The abdomen was much distended and tender, the navel moist, and the granulation tissue covered with pus, though none could be forced from the vessels by pressure upon the abdominal wall.

This case is of particular interest, says Dr. Tuley, because of the following facts: The child was born of a healthy mother who had been in the hospital under the daily observation of the physician and nurses for nearly a month before her confinement; the labor occurred under the most carefully prepared aseptic surroundings, in a hospital where a great deal of abdominal surgery is done, and where no deaths had occurred in more than a year, and that one in another part of the building; it was the first case of obstetrics which had ever occurred in the hospital; the mother had a perfectly normal and uneventful convalescence and had no vaginal discharge before labor; the patient had an experienced trained nurse, on special duty, in charge, and more than the usual care was taken with the dressing of the cord, careful bathing and talcum powder being used. The question has arisen "Where did the infection come from which caused this child's death?" That it occurred through the navel there can be no doubt.

The literature of sepsis of the new-born is very meagre, say Dr. Tuley, but a number of cases have been reported. The following routes for infection have been mentioned. The umbilical cord and its stump are the most frequent points of infection; among others mentioned by Brothers are the following: Accidental injuries or operations with unclean instruments; mammary abscess; tongue-tie or circumcision; abrasions of the buccal mucous membrane, or slight injuries to the genitals or anus; septicæmia of the mother during pregnancy; premature rupture of the membranes, putrefaction of the liquor amnii, and aspiration of this by the child, causing a septic pneumonia; a violent inflammation of the mother's vagina acquired during the last weeks of pregnancy, with premature rupture of the membranes; and septic poisons transmitted from the mother by means of the milk when she has septicæmia following labor.

Jacobi mentions the gastro-intestinal tract as a frequent site of infection, but in his writings decidedly more prominence is given to the umbilicus and its care as a means of the prevention of sepsis. The pus of an ophthalmoblennorrhœa or the decomposing lochial discharge is also mentioned as a cause.

In this case all these sources of infection can be eliminated except the umbilicus. There were no operations done upon the child, the buccal mucous membrane was normal, the mother at no time had symptoms of sepsis, erythrit, or decomposing lochial discharge, and frequent examination of the lungs of the child failed to reveal any lesion. The time of infection can not be decided, says Dr. Tuley, but that it did not occur at the time of tying the cord and its first dressing is certain. There was no septic condition existing in the cord before it separated, as it mummified rapidly and was perfectly dry throughout after the separation. It probably occurred after it became detached, through the fungous navel left, although extra precautions were taken in its care. A possible cause, perhaps, was by septic matter

being carried through a wet napkin by capillarity from the alvine evacuations.

The treatment of sepsis, says the author, is still mainly preventive, and in the majority of cases it can be prevented. The possibility of its occurrence should always be kept in mind, and careful sterilization of ligatures and instruments should be done, as well as of the hands. The ideal ligature, says Dr. Tuley, is the rubber one, and in the ingenious instrument devised by Dr. A. C. Kellogg, with which a small rubber ring is applied to the cord, all danger of sepsis from the primary ligature is obviated, because of its ready sterilization; and hemorrhage simply can not occur.

The after-care of the cord is important; fatty applications should not be employed, but drying powders may be used to facilitate the mummification; a very good formula is one part of salicylic acid and eight parts of pulverized starch.

The care of the cord is of less importance than the care of the stump; every detail in the treatment of any surgical wound should be observed here. Should there develop omphalitis, gangrene of the umbilicus, arteritis, or phlebitis, the most active stimulation is indicated, with prompt attention to the proper cleansing and antiseptic treatment of the stump, the only precaution being the avoidance of carbolic acid as an application. The symptoms of them all are more or less similar, that is, the local appearance of the inflammation at the umbilicus, which is generally bathed in pus; peritonitis is always present to a greater or lesser degree, also pain and tenderness (especially during the bath), and a septic temperature.

**Paralysis due to Inaction.**—In the October number of the *Revue de médecine* M. Féré remarks that excess and lack of exercise are, like excess and lack of excitation, capable of provoking troubles which present striking analogies; for instance, deficiency, like excess, may lead to loss of power.

During the past few years, says the author, overfatigue has been said to play an important rôle in the pathogeny of a large number of nervous troubles. If this is true, it is none the less certain that the effects of overfatigue manifest themselves principally in those individuals in whom congenital or acquired debility has been observed. The primary individual defect shows itself equally well in subjects who suffer from symptoms of overfatigue in the most varied conditions.

Excessive work may cause predominating symptoms in a region of which the activity has been especially brought into play; this is seen in certain professional paralyses, such as hammer palsy; it is also the same in anæsthesia from excessive sensory excitation; but, in general, the entire organism of the individual feels the loss.

If excessive mental excitation is capable of provoking abolition of function, which may be more or less complete and lasting, then the absence of excitation may also produce important troubles. The excitation produced by a certain number of physical agents is indispensable to the maintenance of activity. If excessive excitation by light, for example, may produce local and even general symptoms, the absence of light may also cause symptoms not less important.

Motor activity is accompanied by a certain amount of heat; inactivity, on the contrary, takes away from the organism one of its principal means of defense against cold. Repose favors the harmful effects of cold,

for in individuals who, under the influence of rest, succumb to cold a painful torpor which precedes the lethargic drowsiness is observed. Rest in bed has been observed to cause slackening of respiration and of circulation. M. Guy has seen the pulse decrease from four to five pulsations in a hundred men from twenty to fifty years of age. Immobility retards the absorption of the medicaments which are introduced under the skin.

L. Meyer advocated rest in bed for quieting the agitation of the insane; and Roller, Neisser, and others have called attention to the utility of this treatment. The effects of inaction on psychical activity have been known for a long time; in individuals accustomed to work it may provoke mental troubles. Perfect has remarked that persons who have retired after acquiring a fortune often fall into a state of melancholy. In a general way, says M. Féré, it may be said that the mind suffers more from lack of work than from overwork.

Certain subjects who become reduced in some way to what Claude Bernard calls a life of oscillation, that is to say, particularly liable to external physico-chemical conditions, are more predisposed to the depressing effects of immobility. Like the absence or the excess of excitation, or exaggerated exercise, immobility may provoke in them a functional depression which may lead to paralysis.

**The Late Dr. William M. McLaury.**—The Northwestern Medical and Surgical Society has passed the following resolutions:

*Whereas*, It has pleased Divine Providence to take from us one of our oldest members, a former president of this society, and

*Whereas*, We, the members of the Northwestern Medical and Surgical Society, desire to place upon record our appreciation of the character of our deceased brother; be it

*Resolved*, That in the death of William Muir McLaury this society has lost a devoted, able, and faithful colleague, whose earnestness of purpose and loftiness of motive peculiarly fitted him for the profession which he adorned;

*Resolved*, That the loss which we thus mourn is not limited to our society, or even to our city;

*Resolved*, That we most respectfully and sincerely extend our heartfelt sympathy to his family, wishing for them that consolation which is the outcome of his noble life;

*Resolved*, That a draft of these resolutions be spread upon the minutes of this society, that duplicates be sent to the medical press, and that a copy be transmitted to the family of our deceased friend.

[Signed.] HENRY LING TAYLOR, M. D.,  
President.  
JOSEPH COLLINS, Secretary.

**The Serum Treatment of Typhoid Fever.**—The *Progrès médical* for October 17th contains a review of a recent work on this subject by Dr. M. Funck. It is a complete monograph on the typhoid bacillus and its toxine. In this work the author gives an account of many delicate personal experiments, from the results of which he concludes that the serum of animals which are "immunized" by means of typhoid cultures possesses all the properties that, according to Pfeiffer, are to be found in anticholera serum; that is, it affords protection against typhoid infection in small doses, but not against the *Bacillus coli communis*.

Dr. Funck believes in the therapeutic action of this serum, but he thinks that experiments should be limited to the laboratory for the present, and that the serum treatment of typhoid fever is not yet sufficiently perfect to be tried on man.

This work concludes with a chapter on the pathology of typhoid fever. According to the author, the typhoid bacilli, when introduced into the intestine, swarm in the lymphoid apparatus, where they become engaged in a struggle with the phagocytes, which destroy them, and this destruction causes the freeing of the toxins which is contained in the bacilli themselves.

#### Robinschek's Method of Treating Whooping-cough.—

In the *Lyon médical* for October 11th there is an abstract of an article from the *Bulletin médical de Paris* for September 13th, in which the writer says that this method consists in the introduction into the back of the mouth of a small tampon of cotton saturated with a one-to-one-thousand solution of corrosive sublimate, and pressing it against the lower part of the tongue in such a way that the liquid will bathe the epiglottis and the neighboring mucous membrane.

This method, with which the author has obtained good results, was applied in seventy-one cases of whooping-cough by Dr. Rocco Gentile; thirty-five patients were cured after from three to twelve applications; thirteen were considerably ameliorated, and the others interrupted the treatment or complications supervened which did not depend upon the whooping-cough.

One of the greatest benefits to be derived from this treatment is the rapid cessation of the vomiting which contributes so much to weaken the patients, who lend themselves very readily to the treatment and become rapidly accustomed to the introduction of the tampon.

Gentile has never employed more than one application a day. In a very small number of cases he has observed temporary disturbances, such as hæmorrhages of the conjunctiva and of the ear, buccal ulcerations, and slight fever; but these complications are not serious; in fact, children tolerate mercury easily.

**The Serum Diagnosis of Asiatic Cholera in Man.**—In the *Presse médicale* for September 26th there is an article on this subject by M. Achard and M. Bensaude, who state that they procured the serum of eleven cholera patients during a recent cholera epidemic. The blood was taken from a vein as aseptically as possible and sent to the authors in sterilized tubes carefully corked. Several of the specimens arrived in a state of perfect preservation, the clot not having undergone any liquefaction. In the others the coagulum was dissolved and the blood was somewhat altered, although still perfectly capable of being used; all the more so in that a certain degree of putrefaction does not prevent agglutination from being produced.

In the eleven cases which were examined the agglutination of the cultures of the cholera vibrio was shown ten times by the serum; twice on the first day of the disease, four times on the second day, three times on the third day, and once on the fourth day. The reaction was particularly distinct in two of the patients from whom the blood was taken on the third day. These patients recovered. The authors were able to make an examination of the stools in several cases, and ascertained the presence of the vibrio, so that the bacteriological examination of the intestinal contents distinctly confirmed the indications furnished by the serum.

For the purpose of testing the value of these examina-

tions the same investigation was made with the serum of fifteen persons who were suffering from various affections and with that of a healthy subject. In the majority of these cases no agglutination of the vibrio was produced.

With the blood of uræmic patients, however, the authors observed a small number of masses, but, on the whole, they were not at all comparable to those observed with the serum of cholera patients. Only those reactions which are absolutely demonstrative can be said to have a positive value.

To find this reaction the authors employed the procedure of culture in ten drops of bouillon with a drop of serum. This gave very distinct results; the instantaneous procedure was also successful.

The agglutinant reaction was shown in a more pronounced manner with a specimen of vibrio taken from the stools of a patient who had come under M. Trékaki's observation in the Greek Hospital of Alexandria than with a specimen of cholera vibrio taken from a patient in eastern Prussia. Metchnikoff, in his experimental researches, had also noticed a difference according to the origin of the specimens.

The authors think that these results are of sufficient interest to be reported, and state that, although the conditions may not have been favorable, since the patients themselves were not observed, the phenomenon of agglutination ascertained by them was absolutely typical.

They seem to think that the preceding method of examination might be utilized in a cholera epidemic as a means of diagnosis, especially as the agglutinant property seems to show itself into the serum at an early stage, from the first day in some cases.

**The Treatment of Pulmonary Congestion in the Asphyxial Stage by Cold Applications to the Thorax.**—At a recent meeting of the Société de médecine et de chirurgie pratiques, a report of which appears in the *Journal de médecine de Paris* for October 18th, M. Saint-Yves Ménard stated that he had employed this treatment in the case of a child who was suffering from whooping-cough. The patient presented an intense pulmonary congestion, with dangerous symptoms of asphyxia. The rectal temperature was 101.6° F., the pulse 138, and the respiration 66.

As the symptoms of asphyxia were so alarming, the author covered the patient's chest with cold compresses, which were removed every fifteen minutes. This treatment was continued during the night, and on the following morning the patient was much better. The number of inspirations fell to forty-four, the dyspnoea almost completely disappeared, and the patient recovered.

M. Saint-Yves Ménard thought that in this case the treatment was certainly the cause of recovery. It acted in two ways, he said; first, by withdrawal of the heat; second, by revulsion. It had, furthermore, the power of producing a really extraordinary quieting effect, and was more easily employed than cold baths.

**The University of the State of Missouri.**—Dr. B. Meade Bolton, late of the Philadelphia Bureau of Health, has been appointed professor of bacteriology and pathology.

**The Management of Patients.**—The *Lancet* for October 17th publishes an address on this subject which was recently delivered by Sir Dyce Duckworth before the Lammington Medical Society. One of the main

objects, says the author, in successful management of the sick is to secure the patient's confidence. The psychical influence of the mental attitude thus established is one of enormous, though little understood, value in all therapeutic efforts. It is the attitude which best promotes recovery, and we gladly co-operate with it. But all people have not faith in us or in our art. The qualities of faith and trust are absent from some minds or but little developed; and not seldom do we meet with this distemper in the most subtle and highly trained minds. He regards such a condition (*anurria*) either in respect of worldly or spiritual concerns as a mental flaw somewhat akin to color blindness. We find some persons rejoicing in this disability, while others bitterly regret it. In any case our duty is to act tenderly and to exhibit more, and not less, robustness of belief in our own skill and our art. Such conduct on our part is sometimes contagious and often actively inspiring in seemingly hopeless cases presenting this infirmity. This leads him to say that it is not our duty to pose at the bedside as scientific men. The physician is an artist whose skill is derived through various sciences from careful and accurate observation. He is, or ought to be, a human minister to the ills and needs of the sufferer before him, and not a pedantic professor of abstract physic. In thus endeavoring to secure the confidence of patients we are sometimes exposed to temptations to deviate from a strictly honest and honorable course. We know that such temptations are not always resisted by some men in our ranks, and an easily acquired popularity and a measure of success may be thus achieved. The author says he has, however, lived long enough to learn that such a course never succeeds in the long run, and he sometimes looks back and sees those who once "flourished like green bay trees" now discredited and left far behind. Confidence may be gained, and is always strengthened, by a close and careful attention to the minutest details of the case before us. All hesitation and appearance of uncertainty is to be strenuously avoided. A medical man who can not keenly regard his patient, eye to eye, with firmness and directness, is hardly likely to succeed. And no less must he similarly regard all persons, relations, friends, or nurses, who are dependent on, and should be trustful of, him. With this must be associated gentleness, promptness of decision, a power of command, and a perfectly disciplined temper. All these qualities are requisite in those who have to guide and lead others—naval or military qualities we may call them—but always without any of the overbearing conduct of the martinet. Brightness and cheerfulness, without levity, are always of value in enlisting the sympathy of the sick, and the inlet of a little wit or humor on appropriate occasions does more good than some remedies. Many men of excellent ability and professional skill fail to impress their patients favorably because they lack all sense of humor, and have no power of command or of methodical adaptation of means toward the end in view. Their bedside manner is bad. They make their diagnosis and prescribe, but the patient and the attendants are left in uncertainty both as to the exact opinion formed and as to the precise methods enjoined by the practitioner. Casual directions, with permission to do this or that, or to take this or that, fail to impress anybody, and the result is unsatisfactory. Dogmatism, founded on sound principles, is as good for patients and their friends as it is for students in the lecture room. We must be definite and we must be lucid.

In meeting the ignorance and prejudices of the poor we have to be gentle and forbearing, to show them a more excellent way, and to win them by close personal attention, which is always irresistible. Hospital discipline is beneficial to many of them, and it often reveals, for the first time in their lives, the happiness of having to do what they are told and not what they like. In combating the prejudices of patients who, though not well educated, are not ignorant, it is well to recognize—or, if not, at least to assume—that they have studied the subjects on which they hold strong opinions.

It is sometimes possible to manage a willful patient by falling in with his views so far as is not inconsistent with the best interests of his case. Such a man will occasionally submit at once to treatment on lines which commend themselves to him and on no others. If the proceeding is in no way detrimental and not distinctly contraindicated, we may now and then thus temporize and lose no hold on the patient, whatever be the issue. He will probably in the case of failure readily submit to more orthodox treatment.

A wide knowledge of our common humanity in all its aspects and workings is of much assistance in managing different classes of patients. It is necessary to know how our several patients live, to know how they spend their days, how they eat, drink, work, and amuse themselves.

In prescribing for the poor, he says, we take into consideration what they can procure and appreciate; in prescribing for wealthy and refined patients we must be acquainted with their habits and customs, otherwise we lose their confidence and fail in intelligent management of them. In regard to prescribing medicines, he thinks that many young physicians err in two directions. They either administer drugs in tabloid form or they compose a prescription whose flavor would disgust even a South Sea Islander. There is now no excuse for exhibiting distasteful medicines of any kind, and it is hardly to be wondered at that some patients absolutely refuse to take them, and are thereby shaken in their confidence in the skill and art of their advisers.

The question of consultation, says the author, in grave or puzzling cases is one which occasionally has to be met, and there should be no hesitation in yielding to the desire for a second opinion in many cases which are but slowly amenable to treatment, in which the patient himself is anxious to have further advice. Inspiration and satisfaction are nearly always derived from such consultations, and it is well to show that there is no fear of criticism in regard to what has been done. Confirmation can only increase the patient's confidence and enable the physician to conduct his cases more satisfactorily in all respects. To share responsibility in the treatment of grave cases is always a relief to men who are duly impressed with the seriousness of their calling.

It is not always easy to steer clear of difficulties with the better class of patients. Many of them are disloyal to their advisers, and use them as much or as little as they choose. A physician must always exhibit the courage of his opinions and stand firmly by what he believes to be right against all allurements and any fear of giving offense. He has to learn to be "all things to all men" without making any sacrifice of right principle. This can be done and is done every day by those who have well acquired the art of managing their patients.

It is often a great advantage to be skilled and interested in matters outside our own sphere of work. Such knowledge and dexterity themselves often open the door

to men whose professional knowledge may not be of the highest, but who commend themselves honestly and pleasantly on other grounds to their patients. They will often succeed better than the solemn medical drudge who is learned in the last new methods and reads little beyond medical journals and medical literature, old and new. The author does not in any way deery the constant study of all that happens in our profession; we must maintain that and do more. We should have some hobby of our own, peruse varied literature, and have wide interests in men and things. We shall thus be better equipped and come with brightness and freshness, as well as with "healing in our wings," when we approach the bedside of the sick and ailing.

Traveling is of value in widening our interests and sympathies and enlarging our knowledge of humanity, and it thus enhances the value of our opinion both on medical and other subjects. With all this we need yet more. We have to be circumspect and worthy to retain inviolate the private confidences committed to us. "*Quod tacitum velis, nemini dixeris*" is a motto to be ever before us. Grave matters relating to our patients are often within our knowledge. We note them and seal them up from the busy, inquisitive world around us. Modern society, with its prying and impertinent agents of the press, would have us yield up many secrets confided to us, and then, after gossiping over them, prudishly cry shame on us for disclosing them. Some few among us are easily seduced and trapped by the wiles of the newspaper man, some innocently, but others only too willingly. We should know but one rule in this matter, and it is this: to show such persons outside our doors, politely but firmly and promptly. In this manner we may yet hope to save for our profession some shreds of respect in these terrible days of publicity and mawkish sentimentalism. The bulletins relating to patients which appear in newspapers are now not seldom so impertinent and improper that they constitute a heavy disgrace to such men as issue and sign them, and yet there is no kind of difficulty in checking this unseemly procedure. Such conduct drags down our calling to the rank of advertising tradesmen, and small wonder if decent people seek to belittle it.

**Progress at Craig Colony during the Eight Months since the Opening.**—This is considered to have been the crucial year in the evolution of Craig Colony. All the buildings which were in the Shaker settlement at the time of its purchase by the State for dependent epileptics have been thoroughly remodeled and put into complete order for the reception of patients. A perfect system of water-supply, sewerage, plumbing, heating, and electric lighting has been completed, and on February 1, 1896, the colony was informally opened for patients. A hundred and forty-nine patients have been received thus far, and as soon as the hospital building, now in course of construction, is completed and the west group of buildings provided with heating apparatus, the accommodations will be ready for a population of over two hundred epileptics. In spite of the shortness of the time that has now elapsed since the opening of the colony, two very important facts have become evident: first, that remarkable improvement has taken place in the condition of the patients admitted; and, secondly, that the economic success of the scheme is assured.

**The Effect of Colony Life on the Patients.**—Nearly every patient has gained in weight and in general health. In all cases the epileptic seizures have diminished in

frequency to a marked degree, and in some instances this diminution has been even extraordinary. The expression of the inmates has altered so that, instead of the dull, hopeless look of the almshouse epileptic, one sees on all sides happy faces in which intelligence and hope are being reawakened. The school has been successfully started for fifteen or twenty of each sex. Much of the printing of the colony is now done by two or three epileptics in the colony's own printing office. Carpentry, sewing, painting, etc., are being carried on by the patients. They have their own epileptic blacksmith. Naturally the great work of the inmates of both sexes is in the field and garden. Eighty-three per cent. of the males and seventy-six per cent. of the females have given eight hours' daily labor. This labor has had a great effect upon the income of the colony, demonstrating

**The Economical Value of the Scheme.**—From the report of the superintendent and steward for the year ending September 30th we learn that the products of the farm and garden for the year amounted to \$14,230.20. The cost of maintenance of patients from the date of opening, February 1st, to October 1st was \$28,258.24. The colony has therefore actually produced already one half of the cost of maintenance. Appropriations are asked for this year to increase the productivity of the agricultural department especially, because upon this the economic success of the scheme depends so largely. At the same time, there is most urgent need for accommodations for the hundreds of patients seeking admission. There are nearly a thousand patients still a public charge in the almshouses, insane asylums, and various charitable institutions who need to be provided for at Craig Colony. The managers will ask the Legislature to provide, this coming year, dormitory accommodations for at least three hundred more patients.

**The Influence of Alcoholism on the Growth of Children.**—At a recent meeting of the Académie de médecine, a report of which appears in the *Presse médicale* for October 14th, M. Lancereaux reported two cases which had come under his observation. The first was that of a child thirteen years old. From the age of three years she had taken fifteen ounces and a half of wine a day. At nine years of age she had had typhoid fever followed by purulent pleurisy and pneumonia, and since then had coughed continually. The abdomen had enlarged and the patient had suffered from cramps at night. She had had several attacks of epistaxis. When the author saw her she complained of a tingling sensation in the extremities, of nightmare, and of catarrh. She was no larger than a child of nine years; she was thin and pale, and showed no sign of puberty; the heart was large, and the abdomen, which was very large, was distended with flatus; there was also ascites. The liver and spleen were large, and the urine presented albumin. During the patient's stay in the hospital she showed uræmic symptoms. Under the influence of a milk diet the liver and the spleen diminished considerably a year after her admission, but she did not grow.

The second observation related to a child fourteen years old. When she was twenty months old her mother had given her wine, and from the age of two years she had taken from a pint to a quart of wine a day. When she was eight years old digestive troubles had occurred and, to strengthen the child, her mother had increased the quantity of wine. At six years of age she had had

nightmare and cramps, and the abdomen had begun to enlarge. At the present time she was of about the size of a child of six years. Her height was about thirty inches; her head was small and the expression childish, but she was very intelligent. The thyroid gland was very small, and the thorax was retracted at the upper part and enlarged at the lower part, which was due to the development of the abdominal organs. The abdomen was very large; there was ascites with an abnormal development of the abdominal subcutaneous veins. The heart, liver, and spleen were large. The patient passed a pint of albuminous urine every day. Digestion was badly performed, and the lower limbs were atrophied and paretic. During her stay in the hospital she presented uræmic symptoms. She was placed on a milk diet, and the digestive troubles improved, but she did not increase in size.

M. Lancereaux stated that he had tried to reproduce these lesions by experimentation in two rabbits who were subjected to progressively increasing doses of wine. One had died at the end of twenty days, without presenting any visceral alterations. The other had died after thirty days, and presented hæmorrhage of the stomach. The liver was of a pale grayish color, and the spleen was tumefied.

The histological examination demonstrated traces of an irritating influence in the liver, which were found principally in the central parts of the lobes. The connective tissues of the portal spaces did not present lesions that were very clear, but the subhepatic veins and the capillaries were filled with leucocytes and proliferated endothelial cells. The glandular parenchyma was remarkable for the considerable size of its nuclei, which were vesicular; the cellular protoplasm seemed to be intact.

M. Lancereaux thought it was impossible, in view of these observations, to deny the injurious influence of alcohol on the growth of children, and he said that this was one of the causes of degeneration and depopulation which physicians should energetically fight against.

**The Preparation of Blood for Microscopical Examination.**—In the *Medical Record* for October 17th, Dr. Henry G. Piffard alludes to a branch of blood examination which, he says, is exciting at the present time an increased and well-merited interest. This is the preparation and examination of blood spread in a thin layer and dried on cover glasses.

Blood films are studied from several standpoints and with several distinct objects in view. These are chiefly: To determine the presence or absence of malarial plasmodia; to ascertain the presence or absence of the eosinophile, neutrophile, or basophile granules of Ehrlich; to observe changes and abnormal appearances in the leucocytes and red corpuscles; and to determine the presence and kind, or absence, of micro-organisms. In all these cases the manipulation is substantially the same, with the exception of the stains to be employed.

It is this technics, he says, which he desires to describe in the fullest detail, and with special reference to the slide, the glass cover, the needle, the forceps, the spreading of the film, the fixing and dehydration of the corpuscles, the staining, the mounting, and the optical apparatus, and especially the condenser and objective.

He states that the most satisfactory slides he has been able to obtain are those furnished by Zeiss, at three and a half marks a hundred. These are cut true to size (seventy-six millimetres by twenty-six millimetres), are of

good glass, and are easily cleaned for use with a drop or two of alcohol and a piece of Canton flannel. Zeiss also supplies slides of plate glass at double the price mentioned, but these it is almost impossible to clean with either alcohol or acid. The slides chosen should be of medium thickness. Very thin ones were formerly of service when attempting difficult resolution with extremely oblique mirror illumination. With a substage condenser, however, extreme thinness of the slide is not only unnecessary but undesirable, especially in high-power work. The majority of modern microscopes that are pretended to have any degree of excellence are provided with substage condensers, either N. A. 1 achromatic, or N. A. 1.20, or 1.40 Abbe. Now, these apertures are possible only when there is a layer of cedar oil between the condenser and the slide. The principal microscope makers list their condensers as having the apertures mentioned, but not one of them, so far as he is aware, has the honesty to state that these apertures exist only when they are used with oil immersion, and that when used dry, as is usually the case, the numerical aperture is very much less. If, now, the observer desires to employ an immersion objective of high aperture and to work it at its best, he must put oil on the condenser and focus it for critical illumination. If the slide is an exceedingly thin one, in bringing up the condenser to keep the oil in position he will project the flame image above the plane of the object under examination. If the condenser is now depressed so as to make the flame image coincide with the object, the oil is apt to run out, especially if the microscope is inclined. The condensers are constructed to work with slides of medium thickness, and such slides are the only ones that should be used.

Cover glasses should be selected with great care. Square ones should never be used in the preparation of blood films, because it is exceedingly difficult to obtain a good smear, and it is almost impossible to mount them in a satisfactory manner for permanent preservation.

The most convenient size of round glass will be either three quarters of an inch or eighteen millimetres. American dealers supply the covers in four grades, according to thickness—namely, Nos. 0, 1, 2, and 3. The first two are altogether too thin for general use and should not be used under any consideration. A great deal of blood work can be done better with dry lenses, and the non-adjusting dry lenses in common use are corrected by their makers for a certain definite thickness of cover glasses; and if a thinner one is used, the image obtained will be imperfect. The cover-glass thickness will be found, therefore, to play an important part in blood examinations.

The next step, continues the author, is the proper cleaning of the covers. A small glass dish should be partly filled with battery fluid (water, nine ounces; bi-chromate of potassium, one ounce; sulphuric acid, one ounce), and into this the covers should be dropped, one by one, so that both sides of the cover may be wet by the fluid. After remaining in this for twenty-four hours, the acid is poured off and the covers are flushed *en masse* two or three times with water. Then each should be taken separately and dropped into a dish of distilled water, from which they are to be transferred, singly as before, to alcohol (preferably pure methylic). A most convenient receptacle for the alcohol and covers is a one-ounce, square, screw-capped bottle, in which they may be kept until needed for use.

A very convenient instrument for drawing the blood is a small, straight, surgical needle, several of which

should be kept in a phial of alcohol until needed. For two years or so he has used needles made from an alloy of one part of iridium and two parts of platinum. When required for use the needle is sterilized at a white heat immediately before and also after use. The blood may very conveniently be taken from the tip of the finger, though some writers insist that it is better to draw it from the lobe of the ear. In either case the part should be thoroughly cleansed.

Two forceps are required. One should be of the self-closing variety, with flat, broad points, and with a spring sufficiently stiff to hold the cover firmly against moderate traction. The other may be of any sort that will hold the cover nicely.

A sufficient number, say six or eight, of the covers are removed from the alcohol, thoroughly dried, and laid upon any suitable support, projecting a little beyond it. One of the covers is seized with the self-closing forceps and placed ready at hand. The puncture is then made, and another cover is quickly taken with the second forceps and applied to the droplet of blood as it issues from the wound. The second cover is then laid on the first, and the blood spreads out between them. A common fault with beginners is taking up too much blood; but this will be corrected after a little practice. As soon as the film is spread, the projecting edges of the upper cover are taken between the thumb and the index finger, and the covers are gently slid apart, care being taken to keep them parallel until they are entirely separated. The two covers, with films up, are now laid on a piece of paper to dry, and a second pair are prepared in the same manner. If more than four covers are desired, a fresh puncture should be made. As soon as the films are dry they may be placed in a small envelope and properly labeled. If they are stored in a dry place, they will remain unchanged for a long period. It is better, however, to fix them immediately. If water or any staining fluid was to be applied before fixing, most of the corpuscles would be washed off the cover, and from those that did remain the hæmoglobin would be removed, leaving only the invisible stroma.

With regard to fixing the corpuscles, says Dr. Piffard, the best method, and one which his own experience leads him to prefer, is with heat, rather than any of the other methods that have been employed. For the past year, for this purpose, he has used an electric heater controlled by a rheostat. The covers are heated gradually to about 225° F. and then maintained at this for an hour or more. When the covers are taken from the oven they are allowed to cool gradually and thoroughly before staining.

When ready to stain the covers, they are placed film up on a plate of glass, and covered each with the eosin solution. This is left on for two or three minutes, and washed off with distilled water. When the covers are dry, the methylene-blue solution is applied in the same manner; and when this is washed off and the covers are thoroughly dry they are ready for preliminary examination.

The microscope is arranged vertically, with a clean slide on the stage, and the cover is placed on it, film down and without any intervening medium. Alongside of it, if it is desired, another cover is mounted in balsam and the two are compared. The difference between the two is so striking and absolutely in favor of the dry cover that Dr. Piffard thinks the balsam would be rejected for this purpose. This examination must, of course, be made with a dry lens. A No. 7 Leitz answers very well, but an eighth of an inch or a tenth of an inch objective,

with a numerical aperture approximating 0.90, is still better.

If the examination with the dry lens does not give all desired information, and a further examination is desired with a higher-power immersion, it will be necessary to attach the cover permanently to the slide.

If blood covers are to be mounted to the best advantage, the first step is to procure a turntable. The slide is carefully centred on this, and a thin ring of shellac or other suitable cement spun, corresponding to the size of the cover; a second coat may be applied a few minutes later. A number of slides are prepared in this way, and left for twenty-four hours or more to dry.

When the slides are ready for use, one is taken and held over a flame for a moment or two to expel all surface moisture and to soften the cement a little. The cover in like manner should be flirited over the flame, to expel all moisture from its surface. It is then applied to the cement ring, care being taken to have contact at all points of the circle. When entirely cold, a fresh ring of cement may be spun around the cover, so as absolutely to seal it at every point. The slide is now ready for examination in any manner, and with any dry or immersion lens.

It matters not, says the author, whether we are studying the changes in the leucocytes, hunting up the various granules of Ehrlich, or searching for the elusive plasmodia, the optical picture will be vastly superior and much more instructive than any we can obtain in balsam mounts.

In regard to the substage condensers, he continues, if circumstances restricted him to the use of a single condenser for all purposes, he would choose an achromatic N. A. 1, which may be obtained of excellent quality from Zeiss, Bausch & Lomb, Watson of London, and other makers, costing perhaps ten or twelve dollars more than the customary Abbe. With dry lenses, except those of the very widest aperture, it should be used dry—that is, without oil between the condenser and the slide. By so doing the nominal aperture will be impaired about a third, and thrown a little off its corrections; but even then it will be better than any of the Abbe construction. If used in connection with immersion lenses, oil contact should be used, so as to secure the full aperture. If circumstances permit the expenditure, an additional achromatic of N. A. 1.30 to 1.40 should be added; and for low-power work, an achromatic of low aperture, say N. A. 0.60 to 0.75. In regard to the Abbe condensers that are in such general use, it may safely be said that they are a vast improvement on simple mirror illumination, that was almost the sole dependence before Professor Abbe introduced his simple device. The low cost has undoubtedly been the chief means of its wide introduction, but as an optical instrument of precision it is decidedly inferior to an achromatic of approximate aperture.

Through force of circumstances, fully nine tenths of the laboratory workers employ diffuse daylight as an illuminant, and for the great mass of work to be done it is amply sufficient and satisfactory; but for the most delicate work a well-arranged artificial light is preferable.

At the present time, says Dr. Piffard, the blood offers one of the most inviting fields of investigation, as an aid both to diagnosis and to therapeutics; and he strongly urges on those who design to take it up to pay the strictest attention to what at first may appear to be unimportant technical details.

## Original Communications.

### THE BEST METHOD OF TEACHING OBSTETRICS.\*

By JAMES CLIFTON EDGAR, M.D.

It is a little more than seven years ago that our honored fellow, Dr. Theophilus Parvin, at the thirteenth annual meeting of this academy, made, as the majority of us will recollect, a most earnest plea for practical obstetrics in the courses of instruction given by our medical colleges. It was then clearly shown by him that while the science of obstetrics was admirably taught in many of our American medical schools, the art of midwifery was and had been sadly neglected; that the vast majority of American medical students graduated each year without ever having witnessed, still less having had charge of, a case of labor; that in many medical schools not even the practical diagnosis of pregnancy by palpation and auscultation was taught.

The truth of these statements has never been questioned. Up to that time it had been customary in this country for most medical students to graduate either without any practical knowledge of midwifery, or with such only as they were able to obtain by witnessing an occasional case in a clinic, or possibly by treating women in confinement in their own homes without the supervision or aid of an instructor.

The result was inevitable. The art of obstetrics was learned by the young practitioner often at the expense of serious if not fatal injury to his first confinement cases. During the past decade a revolution has been in progress in the teaching of medicine in this country. The two- and three-year courses are gradually but surely being replaced by four years of instruction; college terms of five, six, or seven months are being lengthened to eight and even nine.

The haphazard theoretical or didactic teaching of the old two-year course has already been largely supplanted by systematic recitations and practical and thorough laboratory instruction. The clinical instruction to large audiences of former years is generally supplemented by practical clinical work performed by small sections of the class. In many medical colleges it is undoubtedly still customary to cling to the old form of lecture delivered to large audiences. It is, however, gradually but surely being replaced by systematic graded courses of practical and clinical instruction.

Has the subject of obstetrics, usually classed as the last of the seven fundamental divisions of medicine, kept pace with the remaining six in this reform? To a certain extent, yes. As to the question whether it has

advanced with the same rapidity as the others, we are compelled to answer in the negative.

The history of medical progress in the past few years certainly points to some reform in the teaching of the art of midwifery, shown in marked improvements in the matter of instruction in colleges already possessing lying-in departments, and in the establishment of new institutions whose main purpose is the imparting of practical instruction, not only to the undergraduate student, but to the graduate physician as well.

Ten years ago not a single medical school in New York city, for instance, required its students even to witness cases of confinement before graduating. At that time there were nine institutions in New York either wholly devoted to lying-in patients, or with lying-in departments attached, and in none of these was systematic instruction in obstetrics given. To-day six medical schools require that each student before graduation shall have attended at least six cases of confinement, and there are some thirteen institutions devoted wholly or in part to obstetrics, five of these giving systematic instruction to students in midwifery.

In spite of these facts, there appears to be no doubt that the teaching of obstetrics generally, throughout the country, is at this time anything but what it should be, and that "clinical instruction is largely conspicuous by its absence."

"The number of great maternity hospitals in this country in which students can receive practical training can be numbered on the fingers of one hand. As a country we are far behind in this matter."\*

The best method to teach midwifery can not be described under any single method, but must, of necessity, be a combined method—a system—a combination of recitations, demonstrations, manikin practice, attendance upon clinics, practical bedside or hospital work, and theoretical lectures, the teaching of the science and art of obstetrics. The classified knowledge of the laws which govern menstruation, ovulation, pregnancy, labor, the puerperium, and obstetric surgery on the one hand, and the intelligent appreciation and practical application of the acquired classified knowledge at the bedside on the other.

Although history tells us obstetric science has had a tardy development, that not until the sixteenth or seventeenth century was it fully established, still, from an educational standpoint, the science has far outstripped the art in the race. May the time soon come—and the indications point to its being not far away—when both shall be equally well taught.

The natural and, as experience teaches us, the best sequence for the student to follow is for him to acquire a working knowledge of the science of obstetrics before he applies himself to the art. This he does in his recitations,

\* Read before the American Academy of Medicine, Atlanta, May 4, 1896.

\* Mann. President's Address. *Transactions of the American Gynecological Society*, No. 20, 1895.

clinics, and demonstrations. Further, we believe it advisable to defer the taking up of the general subject of obstetrics until the pupil has had at least one year's instruction in the medical school, especially in physiology and anatomy. Without this preliminary study the student can not profitably or comfortably digest instruction in the elements of the physiology and pathology

Whatever may be the place of topographical anatomy in courses of anatomy *per se*, its consideration should come early, at the very beginning, in a course of obstetric teaching. It is in a high degree necessary that the pupil shall have mastered, by the time he enters upon his obstetric training, not only the size, shape, and consistency of the normal lower abdominal and pelvic organs, but the relations in space which such organs as the labia, clitoris, meatus urinarius, and hymen, together with their glands, blood-vessels and nerves; the uterus and vagina, kidneys, ureters, bladder, and urethra; the sigmoid flexure, rectum, and anus; abdominal aorta, ovarian, external and internal iliac, and uterine arteries; ovaries, Fallopian tubes, and ligaments of the uterus; pelvic muscles, peritonæum, glandular, vascular, and nerve supply, sustain to one another. If in addition the student has mastered the elements of histology, then, and only then, can he be considered fully equipped to receive elementary instruction from the department of obstetrics, and the head of this department is then free, as he should be, to direct his whole energies to the work which he has been appointed to undertake. After this, the pupil's work in obstetrics should be so systematized as to blend progressively with the work of his remaining three years in the medical school, and render him at the end of that time not only capable of answering the few simple questions found to-day upon the final or State examination paper, but fully competent as well to care intelligently for women in normal labor, and at least to recognize, if not meet, the ordinary complications of the lying-in state, labor, and pregnancy.

Experience has taught us that this end is most surely and thoroughly attained by pursuing some such plan as the following, in the sequence named:

I. Systematic biweekly or triweekly recitations during the second college year.

II. (1) Demonstrations and manikin work; (2) attendance upon obstetric clinics; and (3) laboratory work during the third collegiate year.

III. A resident service in a maternity hospital, which shall include (1) the examination of pregnancy under competent instructors; the actual confinement of patients by the student himself, under rigid supervision in both; (2) "ward" or indoor service, and (3) "out-door" or polyclinic service; (4) the attendance upon the obstetric clinics of the hospital; (5) theoretical lectures (illustrative in character); and (6) recitations subsequently upon the previous practical work performed by the student.

IV. Theoretical lectures (illustrative in character) upon advanced obstetrics.

#### I. SYSTEMATIC BIWEEKLY OR TRIWEEKLY RECITATIONS DURING THE SECOND COLLEGE YEAR.

Attention has been called to the unfortunate custom still prevalent in many medical colleges throughout this country to teach obstetrics to large audiences by means

FIG. 1. Vertical mesial section of the bony pelvis cast in aluminum and mounted by means of a hand screw upon a blackboard and tripod. The bodies of the lumbar, sacral, and coccygeal vertebrae are outlined and numbered. The hand screw permits the cast being set at any angle. An outline of the bony pelvis showing the axis of the pelvic inlet and those of the bony and parturient outlets is permanently sketched upon the blackboard below. (From a photograph.)

of the puerperium, delivery, and pregnancy. He must be familiar with the characters of the various tissues of the hard and soft parts concerned, to which constant reference is made in his recitation year, in terms of microscopic and histological anatomy.

of the didactic or theoretical lecture. Within a few years the attempt has been made by certain institutions to

ject so readily attained as in obstetrics, since the underlying principles of the subject for the most part rest upon the well-known laws of anatomy, physiology, and physics, all of which permit a wide range of illustration.

No department of obstetrics is to-day complete without such means of illustration, and it should be the instructor's duty to make such intelligent use of them as to supplement the labors of the head of the department, relieve him of much of the theoretical work, and, at the same time, better prepare the student for an intelligent appreciation of his subsequent demonstration work, attendance upon obstetric clinics, and finally for his residence in the maternity hospital.

The instructor will do well if, at the beginning of the session, he lays out a schedule for his entire course, gauging his hours of recitation so as to cover the entire field of the subject in the teaching year.

There should be plenty of blackboard space at his command—pelves entire, sagittal and transverse sections of the same, diagrams and charts, carefully selected models, wet and dry preparations, and the more common obstetric instruments.

With a little ingenuity and forethought each individual member of a section of say twenty students may be tested regarding his appreciation of the subject in hand during the recitation hour.

This is readily accomplished by assigning a portion

FIG. 2.—Pelvis and blackboard of Fig. 1 used to demonstrate forceps applied to fetal head at the pelvic inlet and dangers that result from the faulty position of the handles and traction in this wrong direction. (From a photograph.)

supplant this lecture course wholly or in part by the recitation. Since the introduction of this latter method of teaching the shortcomings and faults of the old didactic lecture, still generally in use, have become more than ever apparent. Moreover, the contrast of the two systems has resulted in benefit in quite another way, since it has markedly changed the character and tone of the theoretical lectures which still exist as supplements to the recitational and practical work, raising them to a higher plane, giving them a more practical and illustrative form, and thus making them in every way more helpful to the student.

Although the advantages of the recitation system are more perceptible each year in the better qualified graduating classes, still, we believe the recitation, so far as obstetrics is concerned, can be made of still greater value and interest to the student, even though the instructors be comparatively young men.

It is not sufficient that the section of twenty or thirty pupils be required to learn and recite in a perfunctory manner the principles and laws of obstetric science as set forth in some good text-book in biweekly or triweekly recitations, but these principles and laws must be brought home and rendered real and interesting to him by abundant illustration.

Perhaps in no other branch of medicine is this ob-

FIG. 3.—Pelvis and blackboard of Fig. 1, showing breech presentation with left buttock caught at the pelvic inlet and the dangers of faulty traction on the prolapsed leg in a horizontal plane. (From a photograph.)

of the section to the blackboard, to execute there a diagram, enumerate a series of principles, or write definitions, which are subsequently criticised by the instructor. Another squad is assigned to a number of wet and dry specimens conveniently placed on trays, which the student, after a time given to look them over, is called upon to demonstrate.

Among the wet specimens of especial use at this time are placentae with membranes and cord attached and preserved in alcohol or formalin; ova of the first few months to demonstrate the transition from chorion to placenta, the amnion, the umbilical vesicle, and so on; a uterus showing the decidua of menstruation, another the decidua of pregnancy; also a collection of preserved embryos and fetuses, all of which the student shall be required to inspect or measure, and describe not only the gross appearances and characteristics, but also the chronology of each. Any or all of these specimens the pathologist of a maternity or large general hospital may readily secure.

The dry preparations may include mounted placentae, injected through the vessels of the cords with different colored material or corrosive preparations of the same. These may comprise the normal conditions of the vessels and departures therefrom.

FIG. 1. Pelvis and blackboard of FIG. 1 used to demonstrate sling applied to the breech and faculty direction of traction theorem. Position of doublebushing for breech extraction also illustrated. (From a photograph.)

Still another squad is in the same way assigned to carefully selected models, and the remainder of the class is then questioned upon the subject of the day, enough of the latter part of the hour being reserved for demonstrations and criticisms of those assigned to the blackboard, specimens, and models. Such a plan is by no means difficult to carry out, as experience will prove.

Regarding the models, there is practically no limit to their number, as we show in another place (demonstrations and manikin work), but perhaps the most useful of them all at this time will be found a sagittal section of the pelvis, cast in aluminum, and so mounted upon a portable blackboard as to allow of being fixed in the proper planes of both dorsal and upright positions.

Nothing has been of greater aid to us than this

contrivance, since, with chalk, pelvic planes, angles, curves of bony pelvis, and parturient canal may be clearly demonstrated.

We can not too strongly urge the importance and the benefit to the student of actually handling the wet and dry preparations, pelvis in whole or in part, models, and instruments used in the recitation.

To illustrate the foregoing, take the subject of pelvic deformity, for example. Five students are assigned to manikins with the sacral promontories set to give true conjugates from three inches and three quarters to two inches and a half. A pelvimeter is at hand, and the students are asked to state, after examining the diagonal and true conjugates, the difference between these, the factors influencing this difference, the effect on labor of the contracted pelvis, and the necessity for interference.

Among another squad of five pupils are distributed five copper-plated models of moderate pelvic deformity, and by means of a pelvimeter the students are requested to find the more important diameters, and finally to state the probable cause of deformity, and the effect upon labor of the same.

Still another squad of five pupils is assigned blackboard space, one to enumerate the principal pelvic diameters and their usual lengths, another to demonstrate the three conjugates of the pelvic brim, another the more common kinds of pelvic deformity, another the causes, and still another the methods of delivery.

The remainder of the section can now be quizzed upon some special branch of the subject—for example, the relation between pelvic contraction and malpresentation, position, and attitude, as illustrated by means of models in sagittal and transverse sections; and, lastly, the work of each individual student is inspected, and if necessary criticised, the whole section being appealed to for opinions on difficult points.

## II. (1) DEMONSTRATIONS AND MANIKIN WORK; (2) ATTENDANCE UPON OBSTETRIC CLINICS; (3) AND LABORATORY WORK DURING THE THIRD COLLEGIATE YEAR.

Not even at this time in the student's course is it practical or advisable to attempt to handle classes that exceed thirty.

It is desirable that the position of instructor in obstetrics take on more the nature of a demonstration of obstetrics; that his department consist of a combined museum, manikin, and recitation room, furnished with a generous supply of manikins, models, embryological, anatomical, and pathological wet and dry specimens, charts, diagrams—in short, all the recognized aids to obstetric teaching.

In such an obstetrical laboratory the recitations and demonstrations should be conducted to small sections of the class as above described.

### 1. Demonstrations and Manikin Work.

So far as the demonstrations and manikin work go, biweekly or triweekly meetings, for a period of six to eight weeks, will pretty thoroughly cover the ground.

It is well for the instructor to aim in this section work not only at a systematic course in manikin work, but also at the same time a review of the theoretical work gone over in the second year, giving it, so far as possible, a practical application. This, with a little attention, can be readily accomplished.

The models may be of plaster, or *papier-maché* reproductions of plaster and clay, copper-plated models, or composition, or of a miscellaneous character. With them the parturient canal with its curves; the mechanism of cervical dilatation in primiparæ and multiparæ; the size and shape of the uterus at the several months of gestation; the degrees of uterine, vaginal, and perineal ruptures, and methods of the repair of the latter; involution of the puerperal uterus, as shown in a series of *papier-maché* reproductions of frozen sections; the various forms of pelvic deformity; the action and use of various cervi-

FIG. 5.—Pelvis of Fig. 1. Manual method of measuring the diagonal conjugate. (From a photograph.)

Here again, with a little ingenuity, most, if not all, of the section or squad may be assigned some task to perform during a given hour, so that the student shall take as active a part as possible, leaving little of his time without some occupation.

Such demonstrations and manikin work will call for more apparatus, models, and specimens than was required in the recitations of the preceding year. An abundance of blackboard space is required as before; pelves entire, and in sagittal and transverse sections, must be constantly at hand; three or four good manikins, with a supply of puppets, foetal cadavers (preserved in formalin or alcohol), embryos, fetuses, placentæ, with their membranes in different stages of development, and carefully selected models for use alone and in conjunction with the manikins.

cal dilators; the intra-uterine tamponade; the puerperal curette; the ligature in cervical hæmorrhage; manual dilatation of the os, and many other obstetric conditions. (See *Aids in Obstetric Teaching*, to be published in a subsequent number.) We must insist, however, upon the recognition of the proper place of these models in obstetric teaching, and sound a caution regarding their use. They should be viewed as auxiliaries, as adjuncts, and as a better preparation for subsequent practical instruction; and care must be used that no false or exaggerated impression is conveyed to the student in their use. In another paper we shall describe in detail the manner of their production. As in the recitation system, the same general plan of assigning work may be employed, the student, however, being required to take a more active part.

Thus, by a general illustration and a demonstration form of instruction, much that heretofore has been more or less problematical may be cleared up, and new interest may be given to many obstetric subjects which, by reason of their obscurity and "dryness," proved stumbling blocks to the student, and later to the practising physician.

This is the time and opportunity given the student to acquire that manual training in obstetric procedures which may never recur until he is in active practice, and he should be made to appreciate his advantages.

It is at this time that he acquires the kind of training which gives to the intending physician the practice to make him intelligent and expert in the use of his knowledge; the kind of training which saves the newly

orrhage. Eight or ten students are assigned to manikins, in which are placed leather models of the puerperal uterus. Gauze, volsella, dressing, and needle forceps, needles and ligatures, and specula, all of which are part of the equipment of the department, are at hand.

Each student, with the assistance of a second, and under the supervision of the instructor, is required to pack the uterus with gauze (Fig. 7) and also place a ligature in the apex of the laceration in the neck of the model (Fig. 8). The models are then removed from the manikin, and the manner of gauze packing and the position of the ligature demonstrated and criticised by the instructor. Copper-plated plaster casts of the several degrees of vaginal and perineal lacerations are distributed to other pupils for inspection and subsequent

FIG. 6. Pelvis of Fig. 1. Instrumental method of measuring the obstetrical conjugate directly by means of Farabeuf's pelvimeter. From a photograph.

appointed hospital interne the mortification, in the presence of his seniors, of applying the forceps upside down; the kind of training which causes the interne or newly appointed instructor ever to remember that there is such a thing as a curve to the parturient canal, and that traction with the forceps applied to the brim or on a leg in high arrest of the breech, in a horizontal plane, quite possibly result in disaster to mother and child! For close observation will show that improper and faulty traction with the forceps has cost the lives of more mothers and children than almost any other obstetric operation, in proportion to its frequency. To impress this fact upon the pupil's mind, he must be made to see in what the danger lies. By means of such training the physician's first cases of confinement will be saved much that otherwise would be experimental and crude in the manner of treatment.

Take, for example, the subject of post-partum hæ-

monorrhage. Other students are assigned blackboard space to enumerate origin of hæmorrhage after delivery, mechanism and causes, and principles of treatment.

Such a course can not be considered complete without an occasional demonstration of the diagnosis of pregnancy upon the living subject. Cases of pregnancy may for this purpose be sent in from the dispensary of the institution or from a maternity hospital.

These demonstrations can be made a valuable preliminary to the resident hospital course to follow later. Information obtained by inspection, palpation, and auscultation can be interestingly dwelt upon by the instructor, and appreciated by the student.

## 2. Attendance upon Obstetric Clinics.

An occasional attendance at an obstetric clinic during this third year will be of the greatest assistance in fixing

FIG. 7.—Leather model of puerperal uterus placed in manikin, and used to demonstrate packing of the puerperal uterus with gauze to control post-partum hemorrhage proper, or to secure drainage in atonic or septic conditions of the uterus.

FIG. 8.—Leather model of puerperal uterus placed in manikin, and used to demonstrate treatment of post-partum hemorrhage due to a deeply lacerated cervix.

the theoretical work of the second year, and the demonstrations and manikin work the student takes part in at this time.

If possible, his time should be so laid out as to permit the student to attend over a stated period the obstetric clinics of the hospital, or until he has watched the delivery of several cases of confinement. If it can be arranged for him to take at this time his practice in the out-patient department of the hospital, in the examination and diagnosis of pregnancy, so much the better, for the student can then learn the preliminary principles of cleanliness, thus anticipating his resident service in the maternity.

### 3. Laboratory Work.

Provision should be made for those students who desire special opportunities to study histology, pathology, bacteriology, and embryology, that would not be obtained in the regular courses of the colleges they attend. Little time will be left for such work after the regular laboratory courses in histology, pathology, and bacteriology, consequently advanced research on the part of the student is best undertaken during the vacation intervals or after graduation.

III. A RESIDENT SERVICE IN A MATERNITY HOSPITAL, WHICH SHALL INCLUDE (1) THE EXAMINATION OF PREGNANCY UNDER COMPETENT INSTRUCTORS; THE ACTUAL DELIVERY OF PATIENTS BY THE STUDENT HIMSELF, UNDER RIGID SUPERVISION, IN BOTH. (2) "WARD" OR INDOOR SERVICE. (3) "OUTDOOR OR POLYCLINIC SERVICE. (4) THE ATTENDANCE UPON THE OBSTETRIC CLINICS OF THE HOSPITAL. ALSO (5) THEORETICAL LECTURES (ILLUSTRATIVE IN CHARACTER), AND (6) RECITATIONS SUBSEQUENTLY UPON THE PREVIOUS PRACTICAL WORK PERFORMED BY THE STUDENT.

#### *Resident Maternity Service.*

Without entering into the controversy regarding the actual amount of participation on the part of the student in the practical work of the hospital or of the polyclinic or "outdoor" service, we believe that such obstetric courses should to-day demand not only that the student shall witness the delivery of the patients, but also that he shall personally actually confine the patients, always in the presence of an expert and critical instructor. Moreover, the subsequent care of the puerperal woman and newborn child should rest with the student, always again under a complete system of checks against accident and under the most rigid supervision. That this is not only practical but possible can be abundantly shown by records of thousands of cases of confinement thus managed without accident.

It has been charged against this practical system of teaching, as applied to the medical student, that it carries with it a high mortality rate, and that the pa-

tients treated under such a system are subject to unnecessary exposure.

The first objection is abundantly answered by the records of many such practical systems established years ago in Germany, and by those of several established within the past decade in this country.

The latter objection can only hold good by reason of a lapse in the rigid, critical, and constant supervision on the part of the instructors, which must at all times pervade such practical systems of instruction.

The student will best appreciate and profit by this course if it is taken during his third year, or, better, in vacation time, between his third and fourth years, when he has full leisure to give to it. He should be brought to look upon this practical course as the most valuable and important of his whole obstetrical teaching, for all that he has previously learned is to be tested and fixed in his mind; theoretical deductions are to give place to practical application; he will now not only observe his classified knowledge applied at the bedside, but use and apply it himself.

There is no doubt that students, as a rule, fully appreciate the advantages of such clinical work, although it demands extra time and much work. It is no uncommon occurrence, in one institution at least devoted to education in practical obstetrics, for the student to ask the privilege to remain over his regular period of service, or even to return after a lapse of several months and repeat his practical obstetric course, although he has already more than fulfilled the requirements for graduation.

#### 1. *The Examination of Pregnancy.* 2. *The "Ward" Service.*

It is advisable that the first of the student's observations should be in the examination of pregnancy. The first few days of his service should be rather passive ones. He should be called to witness all the deliveries and operations in the wards or operating room; he should attend such clinical lectures as shall be given; accompany the attending or resident physician in his diurnal rounds, and in addition should spend several hours each day in the out-patient examining room or waiting ward, where, under a competent instructor, he should be required to take an active part in the examination and diagnosis of pregnancy, including pelvimetry, and should, under the supervision of the instructor, be required to fill in properly and sign his name to the histories of pregnancy. It will be well if the record charts used at this time—and later for confinement cases and the newborn child—be fuller and more detailed in their requirements than perhaps the medical records of a hospital would demand. This is intended to bring out the student's faculties of observation, and a wider consideration of the subject than is generally considered necessary. Examinations thus carried out under the eye of the instructor, with attention to minute details,

as well as general observations in the examination and care of even a few cases of pregnancy, labor, and newborn children, will prove of far greater advantage to the student than a much greater number cared for by him without direct instruction and supervision.

No better time than this can be selected to inculcate in the student the principles of obstetrical cleanliness, mechanical and chemical.

Rules and explicit directions for personal cleanliness and disinfection may be printed to advantage in bold type and hung in the examining room, as is the custom in some foreign maternities, notably of Prague. Moreover, by this plan the same rigid cleansing and disinfecting of the hand and forearm is applied to the examination of pregnancy as to that of labor, and to carry it out properly an abundant supply of fresh water, soap, brushes, and mercuric chloride are called for.

With an abundance of material, such examinations of the dispensary and waiting women of the hospital may, after the student has examined several cases under proper supervision, readily be made to resemble the "touch course" of the foreign maternities.

With two students assigned to a case they may be given time, after cleansing of their hands under supervision and according to the rules of the institution, to examine the women both externally and internally. The instructor in charge then examines the cases and questions the students regarding the general condition of the patient, the time of gestation, posture and presentation of the fetus, condition of the mammary glands, anterior abdominal walls, external genitals, pelvic contents, size of the bony pelvis, and departures from the normal in hard or soft parts.

He may now, with great precaution, be permitted to examine several cases in labor in the wards or delivery room; then under rigid and expert supervision he may be allowed to care for the entire confinement. The instructor must stand ready at this time to correct errors in cleanliness, and criticise unskillfulness in management.

Under the supervision of the instructor, as in the examination of pregnancy, the student should be directed in the filling out of a complete history of labor and child, going into the minutest details in order to train his faculties of observation, and to this his name should be signed, so that he may understand that he personally is held to account for the future welfare of the case.

Should the student remain on "ward" duty, the future care of the case is assigned to him, still under supervision of the ward instructor, and the daily observations upon mother and child are taken by him and criticised at the diurnal rounds of the attending or resident physician.

### 3. "Outdoor" or Polyclinic Service.

The systematic training the student has received in the wards renders it possible for him to put this same train-

ing in practice in the care of women in their own homes. Thus, a large class of the poor of great cities, who either can not or will not enter a maternity hospital, may be reached. It is no doubt true, so far as this country is concerned, that while a small proportion of the poor dependent upon charity for proper aid in confinement is cared for in maternity hospitals, by far the greater number remain at home and must be attended there. This outdoor, polyclinic, or tenement-house service on the part of the student can only be rendered practical by an elaborate and carefully supervised system; by the most thorough checks against accident; by an abundant supply of clinical instructors; and by establishing throughout the district to be covered by the service a number of substations to the main hospital building, so situated that one at least shall be easily accessible to each patient on the waiting list, and all in touch with the main hospital by means of telephonic connection.

Here, again, it can be abundantly proved that such a system is not only feasible, but capable of being carried on successfully. Regarding the greater advantage to the student of the outdoor maternity system, as compared with the indoor service, there can be no question. In the former, the pupil, being thrown more upon his own resources and responsibility, becomes no longer a looker-on, an assistant, but, being practically in charge of the case of confinement, he profits by his experience accordingly. The limits of the present paper forbid our enlarging further upon the machinery by means of which such outdoor lying-in services are conducted. Moreover, descriptions of such systems, carried on in Baltimore, Philadelphia, New York, and Boston, have been sufficiently dwelt upon during the past ten years.

### 4. Obstetric Clinics.

With a properly equipped operating room and amphitheatre, each normal or abnormal delivery in the maternity may be made the occasion for an obstetric clinic, all the students on the premises being summoned for the occasion. For this to be properly carried out, it should be demanded of the resident staff that it shall also be a teaching staff, and that a preliminary history of the case, in each instance, should be concisely stated, as well as a careful exposition of each step of the labor or operative procedure.

Such obstetric clinics could readily be made to resemble the diagnosis classes held abroad, as, for instance, in Munich or Prague, where parturient women are rolled into the amphitheatre from the ward or delivery room, and two students are called down from the seats, required to render their hands and forearms obstetrically clean, in the presence and under the criticism of the instructor, then to examine the case, make their diagnosis of pregnancy or labor, presentation, condition of os, membranes, vagina, vulva, bladder, rectum, and hard parts, and finally undergo questioning from the instructor regarding their findings in the case.

Should operation or interference be called for it is to be performed by the instructor; but should the case prove a normal one, the student may be permitted to complete the case, always under the criticism and supervision of the instructor, who should be expected to address not only the students at the case but the entire audience.

Many points of practical interest connected with the management of the second and third stages of labor, the handling of the child, the care of its eyes, the administration of the post-partum douche, the watching of the fundus uteri, the application of an occlusion dressing and abdominal binder, may be brought home in a most thorough as well as interesting manner.

The further conduct of mother and child may rest with the two students confining the case, and they should be held responsible for subsequent departures from the normal condition.

### 5. Theoretical Lectures.

Little time will be left to the pupil for theoretical instruction during his maternity service. This should precede and follow his practical instruction.

What theoretical teaching he does receive at this time should have direct bearing upon the work in hand, and should rather take for its subject abnormal or interesting cases occurring in the recent service of the hospital.

### 6. Recitations.

What we have said regarding lectures applies equally to recitations. One or two a week, however, will prove of the greatest value in fixing the previous practical work of the student. It will be found here that the use of those aids to illustration to which reference has already been made in the college course will prove of untold value in firmly establishing the principles of practical obstetrics in the pupil's mind.

It may be mentioned here that most of these aids, with the exception of the wet and dry specimens, are of such a nature as to be readily kept clean, and thus free from even the suspicion of danger as regards their use in a maternity.

## IV. THEORETICAL OR DIDACTIC LECTURES (ILLUSTRATIVE IN CHARACTER) UPON ADVANCED OBSTETRICS.

A good deal has recently been written regarding the passing of the theoretical or didactic lecture, and the fact that it is less generally made use of than heretofore has, in the foregoing pages, already been alluded to. I can not but believe, however, that, so far as obstetrics is concerned, the theoretical lecture, in a modified form, still has its place and can accomplish much good.

I do not refer to the old-fashioned lecture of fifty-five minutes, devoted to rehearsing the course of a dis-

ease, interspersed with anecdote and clinical experience of the speaker, but we have reference to a lecture—theoretical in part, to be sure, but partly recitation and partly demonstration—which deals with the pathological conditions of more advanced obstetrics, and covers such subjects as abortion and premature labor, extra-uterine gestation, the mechanics and physics of labor, ruptures of the genital tract, puerperal infection, and the rarer forms of pelvic deformity.

Fifteen minutes at the commencement of such a lecture can, to advantage, be given to recitation upon the subject of the preceding lecture, and pathological specimens, models, the blackboard, and the lantern and screen are not to be neglected as means of demonstration and illustration.

In conclusion, I desire to affirm my deep conviction that the subject of obstetrics should be considered in no sense of the term a specialty, but a department of medicine and surgery.

Further, that in the recitations, demonstrations, laboratory work, clinics, practical bedside instruction, and theoretical lectures, already alluded to, the instructor should render a service not only to his listeners but to medicine in general, by rising to something higher than a mere perfunctory performance of his assigned duties, and impress clearly upon his class the fact that midwifery is not a specialty but an integral part, a subdivision only of medicine and surgery.

No part of any subject can be properly understood unless it is studied in its relations to the whole. The interdependence and intimate relationship of these three branches can not be too clearly brought out or too often insisted upon. The light shed by each on the complications of the others is too bright and too valuable to be lost in the obscurity of prejudice and misconception.

Obstetrics to-day, and at all times, should be taught equally as a department of medicine and as a department of surgery.

The day, which fortunately for suffering women has passed, has not faded from the memory of living men—men indeed who took an active part in raising midwifery to its present position, when the obstetrician was refused his equal place by his brother physicians and surgeons, using the words in their narrowest sense, when he was not permitted to operate in the great hospitals of the centres of population, and his art was relegated to the place it occupies now in the hands of the midwife! With the advance of medicine in general during the last half century has come the recognition from every quarter of the kinship of these allied branches, and of the knowledge added to the general fund by the obstetrician's painstaking research. It is just these facts which we claim should be continually brought to the student's attention, in order that he may not in his future career \*

\* Barnes. Inaugural Address. *Glasgow Medical Journal*, December, 1894.

fall into the error of regarding midwifery as a thing apart from general medicine, and, further, that, if his work should chance to lie more particularly in other fields, he may carry with him a just appreciation of an art in which he has been at least thoroughly drilled.

In illustration of what has been said, it may not be amiss to cite a few instances demonstrating that the physiological and pathological states of pregnancy, the puerperium and labor, the therapeutical and surgical measures adopted in handling them, differ certainly not in kind from these conditions found elsewhere. It is only that the greater skill of the accoucheur after long training gives him an advantage readily recognizable. The toxæmia of pregnancy is toxæmia still in spite of its graver import, perhaps, in the danger to the life of mother and child, and its indications in the way of treatment are the same, save for the additional obstetrical treatment. Transient glycosuria disappearing with the termination of labor or the onset of lactation, jaundice, hæmorrhage, cardiac hypertrophy, thrombosis, embolism, offer no essential differences, and, further, exhibit the particular morbid condition in its inception, throwing a light on its ætiology often obtainable in no other way (Barnes, *loc. cit.*). We are too prone to accept the findings in the dead house as cause rather than effect, and to neglect the opportunity furnished by the pregnant state to observe the affection at its outset and thereby discover the true methods of prevention and cure. Metabolism, in both its forms, here furnishes unequalled opening for study to the physiologist. There is much to be learned from observation of the progress of intercurrent disease—*e. g.*, tuberculosis, under the intense vascular and nervous strain of pregnancy. The same is true of skin affections, both as to their nature and ætiology. The so-called "mask of pregnancy" is the chloasma of other states; herpes gestationis is dermatitis herpetiformis; and here the dermatologists may find a clue to the origin of these affections. These statements are equally applicable in the province of surgery and surgical pathology.

Gynecology may, with reason and right, be ranked as a specialty, its technical procedures entitling it to such a place, but not so obstetrics.

Repair of injuries produced by labor, instrumental or manual dilatation of the cervix, symphysiotomy, curettage, fall more naturally to the obstetrician only because of his skill and experience in their operative details, not because the general surgeon is not entirely competent to perform them.

Certain measures, as perforation, cephalotripsy, forceps and version operations, manual removal of the placenta, decapitation, evisceration, correction of malpresentations, positions, and attitudes, closely approach the border line of specialism, but some of these have greatly fallen into disuse since the introduction of other perfected operations offering a chance of life to the child. Cæsarean section itself is merely the removal by the

knife of a foreign body from the interior of a hollow viscus whose outlet is partially occluded.

This argument may appear at first sight a digression from the subject in hand, but reflection will show not only the justice but the necessity of its introduction. His student career is the time when the physician is most impressionable, and when facts are most readily brought home and fixed in his mind.

#### THE CONNECTION OF INTESTINAL AUTOTOXIS WITH CERTAIN COMMON FORMS OF INSANITY.

By ALLAN McLANE HAMILTON, M. D.,

ONE OF THE CONSULTING NEUROLOGISTS TO THE MANHATTAN STATE ASYLUM, NEW YORK;  
CORRESPONDING FELLOW OF THE MEDICAL SOCIETY OF LONDON, ETC.

(Concluded from page 580.)

By far the most suggestive cases in which autotoxis from intestinal disorder plays a part are those of acute excitement, especially where there is rapidly developing incoherence and confusion. These, in my experience, have, as a rule, been associated with corresponding evidences of intestinal disorder such as have been described. Lively and generally fleeting illusions and hallucinations and delusions developing after insomnia, loss of appetite, and constipation, the delusions being unsystematized, are features, and if such derangement be connected with urinary findings of the character I have mentioned, and the clinical evidences of physical disturbance, I think the intestinal disturbance may be always looked upon as a cause.

The more sudden and active are the manifestations when unsystematized delusions or hallucinations are expressed, the more positive are, in my experience, the indications of autotoxis. So characteristic, for instance, are the loquaciousness and incoherence that Jacobson, who has described the toxic insanity of nephritis, has applied the name of "*Verwirrtheit*" to the confusion, which is almost allied to delirium. Acute hallucinatory insanity is often expressed by pseudaphasic confusion, and is often undoubtedly due to the cause I have mentioned, and there are even cases of extreme neurasthenia in which consciousness is more or less affected, and where there is no special delusional system. Occasional remissions of some duration are possible in these forms of general derangement, during which the patient recognizes his false ideas and speaks of them. In some of these cases pseudaphasic confusion is expressed as the result of misleading auditory hallucinations which the patient is unable to correct. To the excited psychoses belong certain short-lived varieties of mental disturbance of this kind attributed to shock, and denominated traumatic insanity, in which such confusion is a characteristic. To this class belongs a case recently seen by me in consultation with Dr. Lusk, of New York.

The patient was a woman, thirty-seven years of age, who went into St. Vincent's Hospital on January 28,

1896. She had had some irregular menstruation with slight uterine hæmorrhages between the menstrual periods, and once or twice in her life had had epileptic convulsions. The condition of the heart and lungs was negative. Abdominal and vaginal examination revealed the presence of a fibrous tumor, which was removed by operation on January 29th, on that day the temperature being normal and the pulse 90, but the urine had a specific gravity of 1.035, and contained abundant urates.

After the operation no untoward results occurred until the next day, when there were restlessness, insomnia, flatulence, and a slight rise of temperature, which continued, so that on the evening of the 31st it had reached 103°. She was troubled with abdominal discomfort, eructations of gas, and increased nervousness. The bowels moved for the first time on February 1st, the amount of feces being very small; on the 2d the enema brought away a large movement. She became flighty on the evening of the 2d, and had delusions and terrifying hallucinations of a persecutory nature; the temperature meanwhile varied between 101.2° and 102°, with broken and uneasy sleep procured only by morphine and chloral.

The urine was now superficially examined, showing an abundance of urates with high specific gravity (1.025), no albumin, and sugar. Her incoherence almost amounted to delirium, and she cried, and was excited and anxious to leave her bed. For several days there was no particular rise of temperature, there being no greater advance than 102.8°, with a corresponding rapidity of pulse. The intestinal disturbance still continued, and was very general. She did not recognize persons, but called them by wrong and fanciful names, and had no idea where she was. She had been fed with nutritive enemata and milk, and on the 14th a critical examination of the urine was made at my suggestion, which disclosed the following appearances:

A moderately large amount of indican and a lowered ratio of preformed and combined sulphates; the combined sulphates measured by the Salkowski-Bauermann method being 0.25 gramme, and the preformed sulphates 0.45 gramme in the urine of twenty-four hours, while the urea was reduced to 11.81 grammes in the same period.

The ratio of uric acid and urea was 1 to 38.

Naphthalin was suggested and given in doses of four grains every two hours, being preceded by calomel and soda. Her condition, which had up to this time been almost continuously one of incoherence, promptly cleared up, and she but occasionally expressed delusions. The next day the temperature fell to 98.8°, and remained normal thereafter. She recognized that she had been irrational, and after the 23d there was little mental disturbance left, the specific gravity of the urine falling and showing a rapid decrease in all abnormal

constituents, while her stools, which had been of a clay color, were well formed and regular. The sulphate ratio became normal, and the total sulphates were properly proportionate to the urea; the ratio of uric acid to urea was 1 to 50.

Another case in which the condition of the urine bore a very close relation to the variation of the mental symptoms was that of a young married lady, who upon two previous occasions, one far apart from the other, had manifested symptoms of an alternating character, there being usually an initial melancholia and succeeding light mania, which increased and had to be controlled by morphine and hyoscyamine. Her periods of mental derangement generally extended over several months, and seemed to bear close connection with a more or less profound disturbance of digestion, and were distinctly modified by the menstrual periods. The attacks of 1893 and 1894 were managed in the ordinary way, and there was a general amelioration of the symptoms and final subsidence, the convalescence occurring after removal from home. In 1895, after a protracted neurasthenia, she was affected with a maniacal condition marked by very great muscular violence, incoherence, and lively delusions, some of which were erotic and unsystematized. So extreme was her condition as to need the services of three nurses, and, despite their uninterrupted care, she became filthy and destructive, tearing her clothes, breaking such objects as she could lay her hands upon, and requiring dangerous quantities of hyoscyne for the production of quiet. Her condition was exceedingly variable, and when she was not engaged in impulsively destroying things about her and assaulting her nurses, she scribbled and wrote incessantly, and there was almost constant verberation. Her bodily condition was one which gave me a great deal of worry, for she rapidly lost flesh, and this despite the fact that large quantities of food of a condensed and apparently suitable kind were taken.

Repeated examinations of the urine and the feces showed a very decided disturbance of gastric and intestinal digestion, and her symptoms kept pace with the variations in these processes. Her mental state, which was most irregular and apparently uninfluenced by anything in her surroundings, revealed an interesting condition of affairs, which was so constant and consistent as to convince me that the insanity was kept up by the absorption of some toxic material. Her periods of excitement and confusion were always attended by a reduction in the amount of urine excreted, by an increase in the ratio of preformed and aromatic sulphates and indican, and by the presence of those signs of impaired digestion which indicated an intestinal putrefactive process. Certain psychical prodromes of attacks after periods of comparative lucidity were nearly always immediately connected with the presence of an increased sulphate ratio. At one time, before this connection was realized,

the prognosis was exceedingly bad, because of the extraordinary condition of physical exhaustion.

This patient had received up to this time nearly all the approved restorative agents and tissue builders that were available, and one twelfth of a grain of the hydrobromide of hyoscyne daily. When this point was reached, the diet was restricted, nitrogenous substances being excluded as far as possible, and thorough intestinal disinfection was obtained by means of charcoal, salicylic acid, and the carbonate of guaiacol, the patient meanwhile being given large draughts of water, and her lower bowels flushed by the long rectal tube, with a mild solution of boric acid. At regular intervals she took calomel purges, and a preparation of the red marrow of the small bones of the calf, to which reference will presently be made. The good result was almost immediate. Excitement subsided, and there was a rapid return of self-control, with the disappearance of the delusions, and a general subsidence of all mental disturbance. Continued and sufficient sleep was obtained for the first time in months, and the patient rapidly recovered. Within a few days after the intestinal antiseptics had been established, the urinary condition became apparently normal, the ratio of sulphates resuming its normal standard, and the specific gravity of the urine was promptly lowered, while the indican disappeared. A distinct and decided gain in color and flesh was inaugurated, and in three weeks after treatment the red blood-corpuscles had increased fifty per cent., while the percentage of hæmoglobin, as measured by the Reichert instrument, rose to 105.

The causation of puerperal fever by the death of the *Bacterium coli* has been demonstrated by Budin, who has studied the febrile disturbance in connection with fecal accumulation. Undoubtedly, many puerperal insanities have some such explanation as this, especially those of the maniacal variety, which often develop in a very few days after parturition. A case I have recently seen was one in which there was absolutely no ascertainable local infection and in which there was no unusual rise of temperature, and a rapid recovery took place after the establishment of intestinal antiseptics.

Alcoholic insanity, as well as other forms, where acute or chronic variations prevail, must, I am convinced, be studied with regard to the conditions of the intestines, and it does not do to ascribe its origin altogether to general exhaustion or to circulatory changes, or to the well-known effects of alcohol upon the nervous tissue, although undoubtedly all these conditions exist at some time or other, and in different cases play a part. If we stop a moment to consider the clinical features of acute alcoholic insanity, we shall find many of the symptoms of a rapidly developing toxæmia, quite apart from that effect upon the nervous system which may be produced by the agent itself. The cerebral hyperæsthesia, rapid changes in perverted perception, the development of the peculiar hallucinations in which rotten substances,

worms, bad odors, or other horrors appear, often figure; the hyperkinesis, cephalalgia, malaise, etc., and the antecedent history of gastric intestinal disorders, the presence of abundant aromatic sulphates, urea and indican in the urine, and possibly skatol, the foul small stools or diarrhœa, the final unstable and changing delusions, exhaustion and death, are suggestive. When we consider that the proteids have passed undigested through the small intestines, and have accumulated below, where they lie enfolded in a congested and feeble gut, it is not difficult to appreciate the fact that they form a rich field for bacterial attack, with the resultant introduction into the system of an amount of toxic material sufficient to produce a most serious change in the functions of the brain and cord. The alcoholic extracts of fecal matter, according to Bouchard, are far more toxic than ordinary putrid matter, so it will be appreciated how readily skatol, indol, and other alkaloids of the feces may be introduced in such quantities as to do much mischief. The successful treatment of the cases of alcoholic insanity that have come under my notice certainly goes far to strengthen this view.

The insanity developing after very acute diseases, especially influenza, is probably primarily dependent upon the intestinal congestion and derangement of the mucous membrane, which is a part of the general disorder elsewhere, but in typhoid fever, where specific intestinal regions are attacked, it does not appear that there is any undue appearance of indol in the urine, although the appearance of post-febrile insanity in this disease would make this seem impossible, at least in a small number of cases.

The practical management of these cases not only includes the provision of an absolutely suitable diet, but the use of antiseptics, and recourse to mechanical means for the purpose of cleansing the gastric tract. That the lower bowel is the seat of infection appears to be very well established by the experiments of Baumann, who found that when a fistula was made in the portion which included the lower portion of the small intestine, there was a disappearance of the indol, phenol, and the other ethereal sulphates from the urine, but that when the intestinal contents were allowed to pass through the lower natural outlet, the putrefactive products were largely increased and their presence was again detected in this fluid. This discovery shows the necessity for thoroughly washing out the lower bowel from as high a point as possible, and a long rectal tube should always be used for this purpose.

Macpherson's plan, tried with some success, is based on a recognition of the fact that when the antiseptic power of the acid of the gastric juice is impaired, there is an indication for the use of intestinal antiseptics with primary recourse to hydrochloric acid. Macpherson resorted first to lavage, which was followed by a dose of calomel at night, a saline purge in the morning, and the subsequent administration of naphthalin in doses, at

first of thirty grains daily, which were increased to eighty grains.

In my selected cases I used a variety of intestinal antiseptics, the list including naphthalin, salol, and the carbonate of guaiacol, charcoal, borax, and the salicylate of sodium. Several cases were put upon small repeated doses of calomel. These drugs were faithfully tried, and although with naphthalin I sometimes obtained excellent results, and in one case of traumatic insanity very prompt ones, I found that upon several occasions it gave rise to diarrhoea, great muscular weakness, and twice strangury, and the urine was colored with hydroquinone.

The administration of phenol or its derivatives may, under some circumstances, mask the results of urinary examination, as was the case in a recent experience. The patient had submitted himself to treatment by a physician for a supposed tuberculous affection, receiving injections of a preparation which contained phenol and pilocarpine. A few days after treatment he became wildly insane and attempted suicide. An examination revealed an entire absence of the preformed sulphates and indican, but a very large amount of combined sulphates. In this case the phenol entirely changed the urinary findings, as it always does. There was no intestinal disorder or there would have been indican, and the conclusion was reached that all the mental derangement was due to the pilocarpine.

Salol was unreliable and of slight service, and was often passed in an unchanged condition in the fæces.

Even with this drug administered in large quantities, it was apt to be found in small round balls in the fæces, and it is therefore recommended that all intestinal antiseptics should be given in small and repeated doses.

Naphthalin, if administered in capsules, which, as a rule, is necessary because of its offensive odor, is sometimes passed in an unaltered state. My experience is that of Herter and Smith, that there is no agent which approaches salicylate of sodium, so far as its antiseptic advantages are concerned, and I have given it in from ten to fifteen grains, thrice daily, and found it of especial value in melancholia and other insanities where the cerebral condition is one of anæmia. The use of this drug, which produces a condition of increased arterial tension, is rather against the theory that uric acid produces cerebral symptoms, for not only is it of service because of its antiseptic action, but in the anæmic brain of melancholia it certainly brings about an improvement through accretion of new blood and nutritive material.

In insanity of a toxic nature there is, as we know, a destruction of hæmoglobin, and a very greatly reduced number of red corpuscles. This condition of affairs is not only met with in the acute insanities due to the absorption of putrefactive products of intestinal indigestion, but in old insanities as well, and Johnson-Smyth found the red corpuscles reduced to 4,070,000 and the hæmoglobin to fifty per cent. in the case of secondary dementia.

So far as the nutrition of the individual is concerned, I have had the best results with a combination which is a rapid producer of nuclein, and when we appreciate the fact that in the majority of these cases there is a destruction of the coloring matter, as well as other blood elements, the provision of some agent rich in this substance is an absolute necessity.

Remedial measures of this kind consisted in the use of a combination of a glyceride of the red marrow of small bones with bullock's blood, the amount of glycerin being regulated both in quantity and temperature so that coagulation does not take place during its preparation. With this preparation I have been enabled to prevent waste, and build up my patients much more rapidly than with any of the other more popular restorative agents, and its use at two of the large hospitals for the insane in New York was attended by an increase of red corpuscles to the extent of fifty per cent., and depressed states were quickly helped.\*

The possible conclusions are, I think, the following:

1. Urines rich in indican contain very little or no preformed sulphuric acid, and are toxic.
2. When the sulphate ratio is materially changed, it is likely to indicate autotoxis in connection with an increase in the amount of combined or ethereal sulphates.
3. Such indications are generally found with acute insanities, in which rapidly developing symptoms occur.
4. Fugacious and changing illusions and hallucinations, unsystematized delusions, confusion and verbiage in connection with insomnia, pallor, intestinal indigestion, constipation, and rapid exhaustion are due to autotoxis.
5. Paranoiac states, or those in which concepts are the features, chronic stuporous conditions, and certain forms of dementia have little to do with the formation of intestinal products of putrefaction.
6. Various post-febrile, traumatic, alcoholic, or drug insanities are those in which autotoxis is most constant.
7. The variations in the excretion of combined sulphates keep pace with the changes in the progress of an established insanity, *accès* and epileptoid attacks being directly connected with putrefactive processes.
8. The most successful treatment consists in lavage, intestinal douches, gastric and intestinal antiseptics by means of hydrochloric acid, borax, salicylate of sodium, charcoal, guaiacol, or naphthalin in small repeated doses. The administration of a combination of the red marrow from the small bones, blood, and glycerin.

## CLINICAL NOTES ON NUCLEIN SOLUTION.

By A. L. A. TOBOLDT, M. D.

PHILADELPHIA.

As so much has already been written about the action of certain animal extracts, especially those of the thyroid and allied glands, it will suffice here to call attention only to the facts that have been definitely proved and are now firmly established in the opinion of the profession—viz., that by their use a certain degree of artificial leucocytosis may be produced, and that, assuming that the white corpuscles are Nature's scavengers of the blood, multiplying their number would naturally lead to the more speedy removal from the body of all noxious principles. It follows, therefore, that these remedies would have a very wide range of usefulness. As my experience with this class of remedies has been confined mainly to the nuclein solution prepared according to the formula of Dr. Aulde, I will enumerate in this paper only cases in which I used this particular preparation. As to comments, I have forbore from making any, confining myself to the simple statement of facts as I have found them, leaving the profession to make what comments it may see fit.

Mr. M., aged thirty-four years, met with an accident while riding a bicycle, which resulted in a fracture of the clavicle and several ribs. The fracture was due to a direct blow from the shaft of a wagon, and the amount of hemorrhage (subcutaneous) was enormous, threatening almost to burst the skin; but under the applica-

tion of cold-water dressing the size of the swelling was materially reduced. When I first saw the patient, about six hours after the accident, I found a lump somewhat larger than a good-sized fist. This was still further reduced by the continued use of cold water, but after five days it seemed to remain stationary, presenting a tumor as large as a fist. After a period of about fourteen days, having taken on various rainbow hues, the skin was beginning to get very thin over the tumor. I then gave the patient tablets of nuclein solution, one third minim every hour, and when I again saw him the next day, I was very much astonished to notice a decided reduction in the size of the tumor, which entirely disappeared in thirty-six hours.

P. K., aged five years. The face and head were covered with boils, due to improper diet. When restricted to a more rational diet, and given one third minim of nuclein solution every hour, it was astonishing to see the boils disappear. After a few days the face was almost clean, and after the lapse of ten days the last boil had disappeared.

Miss McJ., aged thirty years, presented herself for treatment, complaining of great debility, cough with profuse expectoration, hectic fever in the afternoons, followed by cold, clammy sweats. Physical examination revealed marked impairment of resonance over the apex of the right lung; there was also very marked dropsical swelling of the feet, reaching almost to the knees. Upon examination no albumin was found in the urine. This patient, when placed upon one-third-minim doses of nuclein solution every hour, improved so rapidly that she was able to return to her work in a factory after two weeks. When last seen the dropsical swelling had entirely disappeared, and the cough and expectoration had ceased entirely.

Mrs. S., aged thirty years, married, and the mother of three children. First seen November 25, 1895, suffering from very much enlarged abdomen, due to dropsical effusion, dyspnoea, etc. The history and other symptoms pointed to tubercular peritonitis. This patient had been under the treatment of another physician, who had found it necessary to tap her, drawing off, according to the statement of the patient, a very large quantity of fluid. This gave her immediate relief, but, as the fluid again appeared, her physician suggested an operation, which was to be more radical, and, as he hoped, would cure the disease. The operation was delayed on account of the absence in Europe of the operating surgeon, and the doctor was doing all he could to make the patient comfortable in the mean time. This was the state of things when I was first called to see the patient, November 25, 1895. I at once placed her on nuclein solution, three minims given hypodermically every day, and had the great satisfaction to see the swelling of the abdomen diminish very rapidly and to disappear after the lapse of two weeks. The general appearance of the patient had also improved greatly, and after continuing the nuclein solution by the mouth for two weeks more the patient was discharged cured.

Mrs. B., aged thirty-five years, with tuberculosis. Apices of both lungs involved; had repeated hemorrhages with profuse expectoration, hectic, cold sweats, etc. She was placed upon nuclein solution, three minims hypodermically once a day, with an abatement in forty-eight hours and a total cessation after the fourth day of all fever and sweats. The expectoration became less profuse and the patient began to gain in flesh; in two months she increased from ninety-one to one hundred

and one pound, and her present weight is one hundred and five pounds. She is still under treatment; the lungs have cleared up very much and the cough is practically nil.

The case of Mrs. B., aged forty-eight years, is very much like the preceding, only that the improvement has been more marked in the four months of treatment by nuclein solution. The patient has laid on flesh and to all appearances seems well, although she had a slight hæmorrhage, about two teaspoonfuls of blood, a week ago. She is still under treatment. In both these cases practically no other treatment was used than the nuclein solution hypodermically.

Mrs. A., aged thirty-eight years, with tuberculosis of the apex of the right lung, just beginning to break down. The usual symptoms of hectic, sweats, etc., yielded at once to nuclein solution, and after the lapse of three months patient entirely recovered without any further manifestation of the disease after the expiration of nine months.

Mr. S., aged thirty-eight years, had typical typhoid fever. The temperature reached 102° F., and the stools were characteristic, as was also the eruption. Was placed on nuclein solution by the mouth, one third minim every hour, and copper arsenite, one one-hundredth of a grain, every two hours. After the first week the temperature never rose above 99° F., and the case ran a very mild course, the patient returning to his work (saloon-keeper) at the beginning of the fourth week. He returned for treatment at the end of the week, complaining of general weakness, without, however, any rise in temperature or other symptoms of the fever. A carefully selected, generous diet, with tonics, enabled him to return to work after the lapse of two weeks.

L. T., aged five years, presented the symptoms of headache, very high fever (104° F.), slight sore throat, followed within twenty-four hours by an eruption which left no doubt of the nature of the disease. Never having tried nuclein solution in cases of scarlet fever, I thought this a good opportunity. The child had been given a few small doses of calomel when first seen, but as soon as the eruption appeared nuclein solution, one third minim, was given every hour. No improvement was apparent until the evening of the third day, when the temperature showed 101° F., sore throat had disappeared, and the patient appeared bright and inclined to eat. At the end of the week nothing could keep the child in bed, and desquamation was well under way and completed by the end of the second week. In other cases of eruptive fever of similar nature in which nuclein solution was used the effects were gratifying in the extreme.

Mr. T., aged forty-five years, was first seen three years ago, when he presented marked symptoms of diabetes mellitus. Under the usual treatment he improved very much, but returned after a year with all the symptoms in an aggravated form, which again yielded to the former treatment. After the lapse of another year, with all the symptoms worse than ever before, he was placed upon nuclein solution, one third minim every hour, which in two weeks caused a marked diminution in the percentage of sugar—from three to one per cent. The nuclein was continued, and at the expiration of one month sugar had entirely disappeared. A month later he reported with a specimen of urine which again contained a trace of sugar, and being again placed on nuclein the same as before, with the addition of copper arsenite, one one-hundredth of a grain every

two hours, the sugar disappeared entirely, not to return as yet, now six months.

Miss W., aged nineteen years, presented herself for treatment because she was getting so dark complexioned as to resemble a mulatto more than a white girl. This change of complexion was accompanied by general weakness, but otherwise the patient declared herself perfectly well. Being rather pressed for time, and not able to make a thorough examination of the case, I gave her some tablets of nuclein solution, one third minim, directing her to take one every hour, and to report in a week or ten days. To her delight and my surprise, the complexion was a number of shades lighter, and she was feeling very much like her old self. A continuance of the nuclein solution for another ten days completely restored her to her former self, and, as her mother said, she could now go out with her daughter without people making remarks about "that mulatto."

822 N. BROAD STREET.

## AMPUTATION OF A CARCINOMATOUS BREAST DURING LABOR, FOLLOWED BY THE HIGH FORCEPS OPERATION.

By J. IVES EDGERTON, M.D.,

HOUSE PHYSICIAN TO THE NURSERY AND CHILD'S HOSPITAL.

THIS case occurred in the service of Dr. S. W. Lambert, by whose kind permission I report it:

Mrs. E. S., aged thirty-six years, quintipara, was admitted to the Nursery and Child's Hospital September 10, 1896. The history she gave was as follows: Family history negative as to tuberculosis and cancer. Her first and second labors, occurring sixteen and fourteen years ago, were normal. Her third labor, occurring eight years ago, required the use of forceps because of "uterine inertia." The child is now living. Her fourth labor, three years ago, was also instrumental for the same reason. The child is also living.

During the period of lactation following this last labor her right breast became acutely inflamed, and nursing from this breast was stopped in consequence. She nursed, however, from the other breast without any interruption. Neither breast had troubled her during previous lactations. The inflammation did not go on to abscess formation. Since that time her attention has never been called to the breast by reason of any symptoms; she has never had any pain, and she does not remember when she first noticed any peculiarity in the breast. It was during this last pregnancy also that she sustained a fall while walking on the sidewalk. This did not confine her to bed, and she did not see a physician. Shortly afterward she noticed a swelling over the lower part of the back, which has gradually grown. Never any pain, and there were no signs of paralysis at any time. She states positively that her back was normal before this.

Physical examination, at time of admission, showed a well-preserved woman of middle age with no signs of cachexia.

In the lower inner quadrant of right breast was a hard, nodular tumor, movable on the ribs, but adherent to the deep fascia. Nipple and skin over tumor markedly retracted. Several enlarged glands could be felt in axilla, one of them nearly as large as a pigeon's egg. None could be felt in the subclavicular region. In the lumbar

region of the spine was a well-marked kyphosis, involving the third, fourth, and fifth lumbar vertebrae. Her measurements were as follows: Between spines, 26 centimetres; between crests, 30 centimetres; external conjugate, 22 centimetres; right oblique diameter, 26 centimetres; left oblique diameter, 26 centimetres. Promontory could not be felt.

Vaginal examination revealed a very badly lacerated cervix. Its edges were so hard as to suggest malignancy. There was no ulceration evident, however; no bleeding on palpation. Os easily admitted two fingers.

It is well known that malignant tumors of the breast grow very rapidly during the puerperium. Now, the patient, according to her reckoning, was about eight days from term. It was therefore thought best to operate at once, reasoning in this way: that if labor was not directly induced by operation, she would have recovered from the latter before labor came on. Even if it were induced, however, there would still be a fair chance of saving mother and child.

But within two hours of the appointed time for operation the first stage began with strong pains.

It was then thought advisable to do a partial operation; that is, to remove the breast and growth in it, not adding to shock by taking time to remove axillary contents. This was thought justifiable under the circumstances, as it would forestall any functional engorgement of that side of the chest and the consequent rapid growth of the tumor, and a secondary operation could be done later for removal of glands. Accordingly, ether was given, and the breast rapidly removed by Dr. Lambert. The amount of hæmorrhage was slight. Within three hours after she came out of the anæsthetic, labor pains started in again. The cicatricial cervix dilated more readily than was expected, and it is to be noted that there was no hæmorrhage. Second stage started at end of six hours from time of operation. Patient was still suffering somewhat from shock, and pains were weak, so that they did not cause head to engage at end of two hours. As patient was getting exhausted, axis-traction forceps were applied, and child easily delivered in eight minutes. The subsequent history so far uneventful. Wound healed up primarily, with exception of small drain sinus. Milk came into left breast on the third day, and baby was allowed to nurse. Patient was allowed out of bed on the twelfth day. Uterus and cervix appeared normal. The enlarged glands in the axilla have remained the same size, and as soon as patient's condition allows it secondary operation will be done. Microscopically, the tumor proved to be a scirrhus carcinoma.

## THE REMARKABLE ACTION OF ICHTHYOL-GLYCERIN

### ON A SEVERE, APPARENTLY HOPELESS, CASE OF LYMPHANGEIO-PHLEBITIS.

By WILLIAM J. ROBINSON, M.D., Ph. G.

THE powers of ichthylol as an antiphlogistic are certainly well known to the medical profession, but the following case possesses such peculiar features, the action of the ichthylol was so unexpectedly prompt and brilliant, the saving of the man's life was so unquestionably due to that agent, that a detailed report may prove both useful and interesting. The case was kindly referred to

me by Dr. F. M. Nye, of 2089 Lexington Avenue, who gave me the following history:

Mr. A. P., fifty-three years old, teacher, had a slight ulcer on his left leg for about four weeks, which he neglected, thinking it would heal "by itself." But it did not heal by itself, the leg began to pain him and to swell, and one morning, about a week before I was asked to take charge of the case, he felt very ill and unable to get up from bed. In spite of treatment, the limb was getting worse, the pain, redness, and œdema increased, and his general condition became alarming: high fever, chills, anorexia, attacks of syncope, etc. On the 24th of July I took charge of the case and the *status præsens* was as follows, according to my notes: Thin, badly nourished individual; expression, apathetic; color of face and eyes, icteric; tongue coated with thick, brown fur; temperature, 101.8°; pulse, 120, small and compressible. Physical exploration of the chest shows dilatation of left ventricle and slight dullness and liquid râles in lower lobes of lungs, indicative of hypostatic congestion. Subjective symptoms: intense headache, absolute anorexia, constipation, chills twice or three times a day, and occasionally an attack of syncope. The leg is swollen to about double its normal size, of an erysipela-tous red, and exquisitely painful. The long saphenous vein is felt as a hard, rigid cord, exceedingly sensitive to the touch. The ulcer on the leg is small, superficial, and altogether insignificant. The man has two inguinal herniæ, which descend through the canals at the least strain. On the back, at the point of pressure of the truss, slight decubitus. I took the case reluctantly, gave a guarded prognosis, and instituted the following treatment. I washed the ulcer with a 1-to-500 HgCl<sub>2</sub> solution and dressed it with iodoform gauze; it healed slowly and gave no further trouble. I prescribed phenacetine and salol powders, of each 0.3, one three times a day, and the following mixture:

R Spir. glonoini .....	0.8 ;
Tr. strophanthi .....	1.5 ;
Strych. sulph .....	0.015 ;
Spir. vini gall. ....	30.0 ;
Inf. digitalis .....	90.0.

S. 3 ss. ter sive quater in die.

This mixture he took regularly, as the attacks of syncope were undoubtedly relieved and prevented by it. For the leg, I ordered continuous hot fomentations of a three-per-cent. solution of acid. carbolium, with lotio plumbi et opii. The fomentations relieved the pain, but the inflammation did not abate in the least. Instead of the carbolio acid I used creolin, a 1-to-1,000 HgCl<sub>2</sub> solution; I then used carbolio and salicylic-acid ointments, but nothing seemed to be able to check its continuous, uninterrupted, upward progress. Not only the entire limb was intensely inflamed and œdematous, but the left side, to about the level of the umbilicus, was in the same condition. The scrotum and penis attained enormous proportions. He was unable to move, and his sufferings were pitiful in the extreme. On the 30th of July I was hastily summoned at 6 A. M., and found his condition such as to give rise to the gravest apprehension. Pulse, threadlike, 140 a minute; temperature, 104°; first heart sound almost inaudible. I administered a hypodermic of digitalis, strychnine, and nitroglycerin, and ordered a twenty-five-per-cent. solution of ichthylol in glycerin. I enveloped the inflamed parts in lint soaked in that solution, and covered it with cotton and oiled silk. I entertained little hope of his recovery. But when I called

in the afternoon of that day, the picture had completely changed. Temperature, 100°; pulse, 96; the redness and oedema diminished to a remarkable degree. The applications were repeated three times a day. On the next day the swelling had completely disappeared from the leg and genitals; on the back it persisted for a couple of days longer. His convalescence from that day on was uninterrupted. On the 5th of August every trace of inflammation had disappeared, but he felt very weak. Under routine tonic treatment (iron, arsenic, strychnine) he gained strength rapidly, and on the 14th of August he was making his visits to his pupils as usual.

**NOTE.**—The man has since had another attack of phlebitis, this time in the right leg. The symptoms were practically the same as in the first attack, though not quite so severe. The treatment outlined above was repeated, but in addition I ordered very large doses of ichthyol internally—a pill of four grains and a half every hour through the day and two or three times during the night. The result was highly satisfactory; in three days he was quite well. Hard nodules are still to be felt in the course of the veins, but are disappearing rapidly under the internal and external use of ichthyol. I may mention that for external use I prescribed the liquid form of ichthyol (ammonium sulph-ichthyolate), and for internal use the solid form (sodium sulphichthyolate).

112 EAST ONE HUNDRED AND TWENTY-EIGHTH STREET.

## Therapeutical Notes.

**Salicylic Acid in the Treatment of Papilloma of the Vulva.**—M. Louis Mercière (*Tribune médicale*, September 30, 1896; *Lyon médical*, October 18, 1896) uses the following formula:

R Salicylic acid..... from 30 to 38 grains;  
Flexible collodion..... 75 “

M. A few drops are to be applied to eight or ten of the warts at a sitting. On the following day eight or ten more may be treated and a fresh application made to the first ones, and so on till they are all cured.

**For Dyspepsia and Vomiting in Tuberculous Subjects.**—According to the *Gazette hebdomadaire de médecine et de chirurgie* for October 15th, Dr. Barth recommends this formula:

R Prepared chalk, } each..... 3 grains;  
Calcedined magnesias }  
Manganese dioxide..... 1½ grain;  
Powdered belladonna.....  $\frac{1}{100}$  “

M. For one dose, to be taken after eating. If there is severe pain,  $\frac{1}{100}$  of a grain of powdered opium may be added.

**The Treatment of Phreno-glottic Spasm in Sucklings.**—Vergniaud (*Journal de clinique et de thérapeutique infantiles*, 1896, No. 29; *Wiener klinische Rundschau*, October 25, 1896) gives a drop or two of chloroform by inhalation during the spasm, and prescribes the following:

R Tincture of musk..... 20 drops;  
Tincture of belladonna..... 10 “  
Cherry-laurel water..... 120 grains;  
Syrup of orange..... 300 “  
Lactucarium water..... 1,500 “

M. S. Five or six teaspoonfuls to be taken twice a day.

## THE NEW YORK MEDICAL JOURNAL, A Weekly Review of Medicine.

Published by  
D. APPLETON & Co.

Edited by  
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 14, 1896.

### A BOTANICAL EXCURSION TO MEXICO.

IN connection with the Mexico meeting of the Pan-American Medical Congress we lately spoke of the strong probability that physicians who attended the meeting from the United States and Canada would find themselves in a position to learn much about the varied and interesting medicinal plants of Mexico. Under the same heading as that of this article, Mr. John W. Harshberger contributes to the November number of the *American Journal of Pharmacy* an attractive and profitable account of a visit to Mexico.

With reference to the plant communities into which the flora of so large a country may be divided, regard being had to meteorological, geological, and physical conditions, Mr. Harshberger suggests the following classification of Mexican plants: 1. The hydrophytic community, comprising the water plants. 2. The xerophytic community, or desert plants. 3. The halophytic community, composed of salt-loving plants. 4. The mesophytic community, made up of those found in intermediate situations, such as plants of the tropical forests, palm forests, bamboo thickets, temperate deciduous forests, and subtropical evergreen forests, and plants of the arctic, alpine, and prairie regions.

He speaks of the Valley of Mexico as especially suited to the study of plants with reference to the conditions mentioned. He says: “It is an elevated circular valley closed in by two distinct ranges of hills, the oldest, porphyritic, rocks to the north and east, which, before volcanic disturbances began, sloped gradually southward toward the isthmus, and the newer, volcanic, mountains to the south and west, built up in a later period and closing off to the south and east the gradually sloping plain, thus forming the basin-shaped plateau known as the Valley of Mexico. Ajusco, the oldest volcanic peak, stands like a sentinel on the southern rim of the basin, and from its summit to the base of the valley extends a lava bed known locally as the Pedregal. On the southeast rim of the valley rises the ice-capped peak of Popocatepetl (17,780 feet), and to the eastward, connected with the conical volcano, the ridged backbone of Ixtaccihuatl, also snow-capped, considered by geologists to be built of the older porphyritic rocks.

Along the base of the eastern range three fresh-water lakes, Texcoco, Chalco, and Xochimilcho, are found, while the partially drained basin of Lake Texcoco forms an alkaline plain stretching along the Mexican Railroad to the hills, which jut southward into the plain at Guadalupe."

The hydrophytes are found in the lakes and the communicating ditches; the alpine plants, on the summits of Popocatepetl, Ixtaccihuatl, and Ajusco; the xerophytes, on the lava beds; the halophytes, on the alkali plain near Lake Texcoco, in the greatest number on the Gulf Coast; and varied and luxuriant mesophytes, in the rich agricultural soil of the valley. The agave, maguey, or century plant, commonly found cultivated on the plateau of Anahuac, Mr. Harshberger regards as a typical xerophyte. "It stores up in its tissues," he says, "a surprising amount of a sugary water, which exudes when the plant is tapped as the so-called honey-water, or aguamiel. This aguamiel, when fermented, yields the beverage called pulqué, which is consumed in large quantities by the poorer Mexicans. . . . It is obtained from the plant in the following way: When the agave . . . reaches adult size, turns slightly yellow, and begins to shoot up a flower stalk, or before that time, it is tapped by hollowing out a concavity in the core of the plant at the base of the central leaves, which stand upright and are not yet fully expanded. The pulqué-gatherer, with a long hollow gourd pierced at both ends, draws the aguamiel by suction from the concave place as it wells up from beneath. He is clad in cheap cotton clothes and wears a hide apron fastened around his waist and a thick leather knee-pad on his left leg. Then, pressing the spiny leaves aside with his left knee, he pushes one end of his gourd with his right hand into the tapped place and draws upon the other end with his mouth until he has filled the gourd with maguey liquid. He then transfers it to a vessel made of pottery re-enforced by wicker-work, or, as is the usual custom, he pours it into a vessel made of a hogskin. When his skin vessel is full, he carries it to the shed, where for thirty-six hours the agave juice is allowed to ferment, changing during this process from a yellowish-looking fluid to a milk-white, yeasty-looking liquid. It is a very refreshing and wholesome drink for those high altitudes if taken in moderation."

Pulqué, says Mr. Harshberger, keeps fresh only for a day, when it begins to turn sour. The sour liquid is distilled and yields, according to the process used, either mezcal, tequila, or aguardiente de maguey, all of which are powerful alcoholic drinks. A Mexican Indian addicted to their use, he says, can drink a glass

of any one of them without effect, but two or three glasses will make him demoniacally crazy. We have not space to follow Mr. Harshberger's article further, but must content ourselves with commending it to the reader.

#### EXTENSIVE ACCIDENTAL VACCINATION.

In the *Wiener klinische Wochenschrift* for October 29th Dr. Gustav Riether, an assistant physician to a foundling asylum in Austria, gives an account of the case of a girl baby, seven months old, that was received into the asylum with nearly three hundred vaccinal pocks covering the upper two thirds of the face and encroaching on the chin. This surface had been affected with eczema, and the eczematous area had been inoculated with vaccinia accidentally, it was supposed, from a child that had been vaccinated about three weeks before and had been cared for by the same foster-mother. The eyes were closed, there was an abundant fetid oozing, and there seemed to be great itching. The child failed rapidly and died in a week. A cut made from a cast of the child's face gives a very fair idea of its appearance.

Dr. Riether is aware that the extensive spreading of vaccinal lesions over a surface denuded of epithelium is not a very uncommon occurrence, but in the literature at his command he has found accounts of only four cases that he thinks fairly comparable to his own. He is careful to distinguish the condition from the rare one of a true vaccinal eruption, a "breaking out" of vaccinal lesions, or of other cutaneous lesions, on the sound skin, as the expression of the systemic effect of vaccination—the so-called generalized vaccinia—but it seems to us he is unwise in proposing for the state he describes the names *vaccinia* (already in use among English-speaking physicians to denote the vaccine disease in its ordinary form) and *vaccinosis* (*Vaccinose*), although to the last-named appellation there may not be any special objection.

#### MINOR PARAGRAPHS.

##### A NEW SPANISH JOURNAL.

WE have received one of the early numbers of the *Revista Médica Rural*, published in Blanes, in the province of Gerona, and edited by Señor E. Alabern and Señor M. Balvey, licentiates. It is a semimonthly journal of general medicine. We wish it success.

##### ITEMS.

**The American Association for the Study and Cure of Inebriety.**—The twentieth anniversary of the publication of the *Journal of Inebriety*, and the twenty-sixth year of the Association for the Study and Cure of Inebriety, will

be celebrated by a memorial meeting at the New York Academy of Medicine, on Friday evening, November 20th.

The following addresses and papers will be presented: An Historical Review of the First Meeting of the Association and its Papers and Discussions, by Dr. Lewis D. Mason, of Brooklyn; The *Journal of Inebriety*: its Organization and Growth; the Early and Later Literature, by Dr. T. D. Crothers, of Hartford, Connecticut; The First Asylum for the Care of Inebriates and its Founder, by Dr. Charles H. Shepard, of Brooklyn; The First State Asylum for Pauper Inebriates and its Work, by Dr. M. E. Hutchinson, of Foxboro, Massachusetts; The First Efforts to Treat Opium Cases in Asylums, by Dr. J. B. Mattison, of Brooklyn; The First Home for the Transient Care of Inebriates, by Dr. V. A. Ellsworth, of Boston; Empiric and Charlatan Efforts to Cure Inebriates for the Past Quarter of a Century, by Dr. N. Roe Bradner, of Philadelphia; The History and Influence of Alcohol in Medicine in Modern Times, by Dr. I. N. Quimby, of Jersey City; and The Origin and Growth of Asylums for Inebriates in Great Britain, by Dr. Norman Kerr, of London.

**Infectious Diseases in New York.**—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 10, 1896:

DISEASES.	Week ending Nov. 3.		Week ending Nov. 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever.....	27	6	22	2
Scarlet fever.....	83	5	91	4
Cerebro-spinal meningitis...	0	0	1	1
Measles.....	41	2	62	3
Diphtheria.....	194	20	213	27
Tuberculosis.....	99	105	161	88

**The Health Department and the Serum Diagnosis of Typhoid Fever.**—Dr. Hermann M. Biggs, the pathologist and director of the bacteriological laboratory, in a communication, dated November 7th, to the Hon. Charles G. Wilson, president of the city board of health, says:

"I desire to direct the attention of the board to a new laboratory method for the diagnosis of typhoid fever which, judging from the data available at the present time, promises to be of very considerable practical value in the diagnosis of early or ill-defined cases of this disease.

"The investigations of Pfeiffer and Widal have shown that the blood of persons suffering from typhoid fever, when mixed with active cultures of the typhoid bacillus, has the power of arresting the active movement of these organisms and of producing peculiar and characteristic clumping of the bacilli. It has been shown that this reaction occurs frequently very early in the course of the disease, that it is found throughout its course, during convalescence, and often for a considerable period after complete recovery. It does not occur with other organisms than the typhoid bacillus, and it does not occur with cultures of the typhoid bacillus when the blood of persons suffering with other diseases is employed. As has been shown by Widal and Johnson, this reaction occurs as well with specimens of dried blood as with fresh blood, and thus can be employed practically for the diagnosis of this disease in municipal laboratories. Observations on this matter which have been in progress in the laboratories of this department for some time past have thus far confirmed the conclusions of previous investigators.

"In order that more numerous data shall be at the command of this department and that physicians of New York may at the earliest moment have facilities for testing the reliability of the observations thus far made, I would respectfully recommend that arrangements be made to place facilities for such examination at the command of all physicians in this city, it being distinctly understood that this action of the department is for the purpose of gaining information on this important subject and at the same time of placing at the command of physicians opportunities for observing the results. If the data already obtained are entirely confirmed by subsequent observations, this method

will undoubtedly prove of great service in the diagnosis of early and obscure cases of typhoid fever.

"Should this action be determined upon, circulars of information as to the method of collecting blood and slides for this purpose may be left at the depots already established for the collection of diphtheria culture tubes and the distribution of diphtheria antitoxine."

Accordingly, the following resolution was adopted by the board at a meeting held on November 6th:

Resolved, That the recommendations of the director of the bacteriological laboratories of this department, contained in the communication dated November 6th, be and are hereby approved, and that he is hereby authorized to place facilities at the command of physicians in this city for the diagnosis of cases of typhoid fever, in accordance with the method prescribed in said communication.

The following notice to physicians has been issued by Dr. Biggs:

"Circulars of information regarding the method employed and slides for collection of blood may now be obtained at the various druggists' where diphtheria culture tubes are kept. Physicians desiring to make use of this method in the diagnosis of early or obscure cases of typhoid fever can procure these, and, after collection of blood as described, may leave the slides, with the data relating to the case, at the various depots. They will be collected each day, examined the following day, and the report of the result forwarded to the physician."

**The American Association of Obstetricians and Gynecologists.**—At the ninth annual meeting, held in Richmond, Virginia, the following officers were elected for the ensuing year: President, Dr. James F. W. Ross, of Toronto; vice-presidents, Dr. George Ben Johnston, of Richmond, and Dr. John C. Sexton, of Rushville, Indiana; secretary, Dr. William Warren Potter, of Buffalo; treasurer, Dr. Xavier O. Werder, of Pittsburgh; members of the executive council, Dr. Charles A. L. Reed, of Cincinnati, Dr. Lewis S. McMurtry, of Louisville, Dr. A. Vander Veer, of Albany, Dr. J. Henry Carstens, of Detroit, and Dr. William E. B. Davis, of Birmingham, Alabama. The next annual meeting was appointed to be held at the Cataract House, Niagara Falls, N. Y., on Tuesday, Wednesday, Thursday, and Friday, August 17, 18, 19, and 20, 1897.

**The Buffalo Academy of Medicine.**—At the last meeting of the Section in Medicine, on Tuesday evening, the 10th inst., the following papers were to be read: A Case of Chronic Diarrhoea successfully Treated by Lavage, by Dr. S. A. Dunham; The Importance of Early Attention to Hypertrophy of the Naso-pharyngeal Lymphoid Tissue, by Dr. F. W. Hinkel; and The Reflex Effects in the Pharynx and Mouth of Intranasal Disease, by Dr. Horace Clark.

**A Lecture on the Byzantines** was given before the Deutschergesellig-wissenschaftlicher Verein by Dr. Achilles Rose on Thursday evening, November 12th.

**The Death of Professor H. Newell Martin**, late of the faculty of the Johns Hopkins University, Baltimore, took place in England on Thursday, October 29th. Dr. Martin was forty-eight years old at the time of his death. He was a native of Ireland.

**Dr. Fowler's Work on Appendicitis.**—We notice that a German translation of Dr. George R. Fowler's work, with an introduction by Professor Landrer, of Stuttgart, is announced in Berlin.

**Changes of Address.**—Dr. T. Bull, to No. 472 West One-hundred-and-forty-seventh Street, New York; Dr. S. M. Johnson, to No. 51 West Ninth Street, New York; Dr. Boardman Reed, from Atlantic City, New Jersey, to No. 1831 Chestnut Street, Philadelphia (for the winter).

**Army Intelligence.**—Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 25 to November 7, 1896:

The following named recently appointed assistant surgeons will repair to this city (Washington) and report in person on November 4, 1896, to the president of the Army Medical School for the course of instruction prescribed

in General Orders No. 78, September 22, 1893, from A. G. O.:

DARNALL, CARL ROGER, First Lieutenant;  
 DUTCHER, BASIL HICKS, First Lieutenant;  
 FULLER, LEIGH AUSTIN, First Lieutenant;  
 KEMP, FRANKLIN MIDDLETON, First Lieutenant;  
 RICHARDS, WILLIAM EVANS, First Lieutenant;  
 SKINNER, GEORGE ALFRED, First Lieutenant.

MOSELEY, EDWARD B., Major and Surgeon, is granted leave of absence for four months, to take effect upon being relieved from duty at Fort Monroe, Virginia.

STONE, JOHN H., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Leavenworth, Kansas, and ordered to Fort Riley, Kansas.

#### Promotions.

To be Assistant Surgeons with rank of Captain, after five years' service, October 31, 1896:

FISHER, HENRY C., First Lieutenant and Assistant Surgeon;  
 KIEFFER, CHARLES F., First Lieutenant and Assistant Surgeon;  
 SHAW, HENRY A., First Lieutenant and Assistant Surgeon.

#### Appointments.

To be Assistant Surgeons with the rank of First Lieutenant, October 26, 1896:

DARNALL, CARL R., of Texas;  
 DUTCHER, BASIL H., of New York;  
 FULLER, LEIGH A., of New Jersey;  
 KEMP, FRANKLIN M., of New York;  
 RICHARDS, WILLIAM E., of Mississippi;  
 SKINNER, GEORGE A., of Minnesota.

#### Naval Intelligence.—Official List of Changes in the Medical Corps of the United States Navy for the Week ending November 7, 1896:

BLAKEMAN, R. S., Assistant Surgeon. Detached from the U. S. Steamer Vermont and ordered to the U. S. Steamer Boston.

CARPENTER, D. N., appointed as Assistant Surgeon and ordered to the Naval Laboratory and Department of Instruction, New York.

FARENHOLT, A., Assistant Surgeon. Detached from the Mare Island Naval Hospital and ordered to the U. S. Steamer Oregon.

HENEBERGER, L. G., Surgeon. Ordered to the U. S. Steamer Maine.

KENNEDY, R. M., Passed Assistant Surgeon. Detached from the U. S. Steamer Patterson, ordered home, and granted three months' leave of absence.

LUMSDEN, G. P., Surgeon. Detached from the U. S. Steamer Yorktown, ordered home, and granted three months' leave of absence.

NEILSON, J. L., Medical Inspector. Detached from the U. S. Steamer Maine and placed on waiting orders.

PAGE, J. E., Passed Assistant Surgeon. Detached from the U. S. Steamer Boston and ordered to the U. S. Steamer Yorktown.

PALMER, S. B., Assistant Surgeon. Detached from the Naval Laboratory, New York, and ordered to the U. S. Steamer Vermont.

PLEADWELL, F. L., Appointed as Assistant Surgeon and ordered to the Naval Laboratory and Department of Instruction, New York.

ROTHGANGER, G., Passed Assistant Surgeon. Detached from the U. S. Steamer Oregon and ordered to the U. S. Steamer Patterson.

WHEELER, W. M., Assistant Surgeon. Detached from the U. S. Steamer Franklin and ordered to the Naval Hospital, Mare Island.

#### Marine-Hospital Service.—Official List of the Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the Sixteen Days ending October 31, 1896:

PURVIANCE, GEORGE, Surgeon. Placed on waiting orders from November 3, 1896. October 27, 1896.

SAWTELLE, H. W., Surgeon. Detailed to represent the service at the Pan-American Medical Congress, to be held in the City of Mexico. October 28, 1896.

WHEELER, W. A., Surgeon. Granted leave of absence for three days. October 16, 1896.

PECKHAM, C. T., Passed Assistant Surgeon. Directed to proceed from Port Townsend, Wash., to Detroit, Mich., for duty. October 27, 1896.

GLENNAN, A. H., Passed Assistant Surgeon. Granted leave of absence for nine days from December 23, 1896.

PETTUS, W. J., Passed Assistant Surgeon. To assume temporary command of the service at Norfolk, Va., in addition to his other duties. October 24, 1896.

MAGRUDER, G. M., Passed Assistant Surgeon. Detailed as inspector of immigrants at Galveston, Texas. October 24, 1896.

WERTENBAKER, C. P., Passed Assistant Surgeon. To proceed from Delaware Breakwater Quarantine to Philadelphia, Pa., for temporary duty. October 16, 1896.

YOUNG, G. B., Passed Assistant Surgeon. Leave of absence extended five days. October 16, 1896.

NYDEGGER, J. A., Passed Assistant Surgeon. To proceed from South Atlantic to Brunswick, Ga., Quarantine for temporary duty for thirty days. October 26, 1896.

NORMAN, SEATON, Assistant Surgeon. Granted leave of absence for five days. October 22, 1896.

PROCHAZKA, EMIL, Assistant Surgeon. To proceed from Cairo, Ill., to Delaware Breakwater Quarantine for temporary duty. October 16, 1896.

CUMMING, H. S., Assistant Surgeon. Relieved from duty at Evansville, Ind., and directed to rejoin station on expiration of present leave, at New York, N. Y. October 22, 1896.

#### Resignation.

HAMILTON, JOHN B., Surgeon. Resignation accepted to take effect November 13, 1896. October 16, 1896.

#### Society Meetings for the Coming Week:

MONDAY, November 16th: New York Academy of Medicine (Section in Ophthalmology and Otolaryngology); New York County Medical Association; Hartford, Connecticut, Medical Society; Chicago Medical Society; Boston Society for Medical Improvement; Cleveland Society of the Medical Sciences.

TUESDAY, November 17th: New York Academy of Medicine (Section in General Medicine); New York Obstetrical Society (private); Buffalo Academy of Medicine (Section in Pathology); Ogdensburg, N. Y., Medical Association; Syracuse, N. Y., Academy of Medicine; Medical Societies of the Counties of Chemung (semiannual), Kings, and Livingston (quarterly), N. Y.; Baltimore Academy of Medicine.

WEDNESDAY, November 18th: Medico-legal Society, New York; Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark).

THURSDAY, November 19th: New York Academy of Medicine; Brooklyn Surgical Society; New Bedford, Massachusetts, Society for Medical Improvement (private).

FRIDAY, November 20th: New York Academy of Medicine (Section in Orthopaedic Surgery); Brooklyn Medical Society; Baltimore Clinical Society; Chicago Gynecological Society; St. Louis Academy of Medical and Surgical Sciences.

SATURDAY, November 21st: Clinical Society of the New York Post-graduate Medical School and Hospital; St. Louis Medical Society.

#### OBITUARY NOTES.

Edward H. Parker, M. D., of Poughkeepsie.—Dr. Edward Hazen Parker died on Tuesday, November 10th, at his home, in Poughkeepsie, aged seventy-three years. He was a graduate of the Jefferson Medical College, of the class of 1848. A number of years ago he practised in New York and was a member of the faculty of the old New York Medical College. For many years before his death, however, he had lived in Poughkeepsie. He had much more than a local reputation as a physician, and was known as a forcible writer and an agreeable speaker. On Thursday evening, November 12th, the Medical Society of the County of Dutchess held a special meeting in respect for his memory.

## Births, Marriages, and Deaths.

### Married.

BENNETT—LAIDLAW.—In New York, on Thursday, November 5th, Dr. Imlay Bennett and Miss Edith Laidlaw.

CANTELOU—HILL.—In Edgefield, South Carolina, on Thursday, October 29th, Mr. Joseph Cantelou and Miss Tweedie Hill, daughter of Dr. J. Walter Hill.

CROSBY—DELAFIELD.—In New York, on Wednesday, November 11th, Mr. Frederick V. S. Crosby and Miss Julia Floyd Delafield, daughter of Dr. Francis Delafield.

HEBERT—DUCOTE.—In Cottonport, Louisiana, on Wednesday, November 4th, Mr. Clarence Hebert and Miss Ethel Lea Ducote, daughter of Dr. Cleophas J. Ducote.

LONGENECKER—DAVISON.—In Brooklyn, on Wednesday, October 28th, Dr. William Roger Longenecker and Miss Pearl Davison.

RUOFF—GRAMM.—In New York, on Thursday, November 5th, Dr. William Ruoff, of Philadelphia, and Miss Louise Gramm.

SCOVIL—KESSLER.—In Richmond Hill, N. Y., on Thursday, November 5th, Dr. William Thomas Scovil and Miss Hattie Augusta Kessler.

### Died.

LANGAN.—In Oswego, N. Y., on Thursday, November 5th, Dr. John T. Langan, aged forty years.

LYONS.—In New Orleans, on Saturday, November 7th, Dr. John J. Lyons, aged sixty-three years.

PARKER.—In Poughkeepsie, on Tuesday, November 10th, Dr. Edward Hazen Parker, aged seventy-three years.

RANKIN.—In Newport, Rhode Island, on Monday, November 9th, Dr. Francis Huntington Rankin, in the fifty-first year of his age.

## Book Notices.

*The Physiology and Pathology of the Cerebral Circulation.* An Experimental Research. By LEONARD HILL, M. B., Hunterian Professor, Royal College of Surgeons, London, etc. London: J. & A. Churchill, 1896. Pp. xvi+208. [Price, \$4.20.]

PROFESSOR HILL's work demonstrates two things, the usefulness of endowments for scientific research and the inestimable value of physiological experimentation to an understanding of pathological conditions. The work of five years, attractively summarized in this book of two hundred pages, was largely performed while the author was holding the research scholarship of the Grocers' Company. It covers a field that is interesting alike to the physiologist, the pathologist, the clinician, and the surgeon. The problem that Hill set himself to solve was this: Given a skull of rigid bone, inclosing an incompressible brain; given arteries entering the cavity, permeating and anastomosing in the pia mater, then entering the nervous matter, and ending in capillaries; given veins that arise from the capillaries and form huge cranial sinuses, which in turn give origin to outgoing veins; and, finally, given a minute quantity of cerebro-spinal fluid pervading the small space between the brain and its bony case—what is the hydrodynamics of such a cranium? By trephining the cranial wall and connecting the cavity with a manometer Hill measured the intracranial (subdural) pressure; by a similar method applied to the torcular Herophili he measured the cerebral venous pressure; and these data were compared with the general arterial and the general venous pressures of the systemic circulation. His experiments, which cover a very wide field, confirm

and refute many old ideas, present a host of new results, and suggest new points of view, some of which are here presented.

The cardiac and respiratory movements of the brain exist in the closed cranium. The subdural and subarachnoid spaces are physiologically one. The pressure of the cerebro-spinal fluid is normally the same as that of the blood in the cerebral veins. Irrigation of the brain and spinal cord through one trephine opening is possible and harmless. Irrigation of the meninges in such conditions as meningitis might be employed as safely as irrigation of the peritonæum. Removal of the cerebro-spinal fluid gives place to a serous transudation. No pathological increase of cerebral tension can be transmitted by the cerebro-spinal fluid, because of the relation of the latter to the venous pressure. No evidence of the existence of cerebral vaso-motor nerves or of a local vaso-motor mechanism was found. Intracranial pressure varies directly with general venous pressure and proportionately with arterial pressure. The volume of blood in the brain in physiological conditions is only slightly variable. The cerebral circulation is controlled by the bulbar vaso-motor centre acting on the splanchnic area. This vaso-motor mechanism compensates for the important effects of gravity on the circulation, and the compensation is more complete in upright animals, *e. g.*, monkeys and probably man, than in animals that walk on all fours. Chloroform paralyzes this compensatory vaso-motor mechanism rapidly; ether, slowly. Elevation or rhythmic compression of the abdomen and thorax compensates for chloroform paralysis and restores the animal from collapse. The symptoms of cerebral anæmia are exactly comparable to those of asphyxia. Probably both common carotid arteries can be safely tied in man if each artery is gradually closed by a screw clamp with time intervals between successive compressions. Sleep is accompanied by cerebral arterial anæmia and venous congestion, and is directly related to the activity of the splanchnic vaso-motor area. The brain is not, as Mosso thought, the seat of active metabolism. A foreign body within the cranial cavity increases cerebral pressure only by acting on the vessels. A small opening into the cavity does not necessarily relieve compression. Either the foreign body must be removed or a large opening made, sufficient to allow of expansion of the cranial contents.

Besides these conclusions, a host of others are presented, and the applications of the scientific results are constantly pointed out. The various conclusions do not appear to be equally well supported by the experimental facts, and the inference regarding slight brain metabolism is hardly warranted. The work, however, marks a distinct advance in a difficult field of research, and the clinician and the surgeon can hardly fail to learn much from it.

*Lehrbuch der Haut- und Geschlechtskrankheiten für Aerzte und Studierende.* Von Dr. MAX JOSEPH. in Berlin. Zweiter Theil. Geschlechtskrankheiten. Zweite vermehrte Auflage. Mit 29 Abbildungen im Text und einer farbigen Tafel. Leipzig: Georg Thieme, 1896. Pp. viii+416.

THE second edition of Joseph's work on skin and venereal diseases, of which the present volume deals with the latter class of ailments, is, like the first edition of four years ago, an exhaustive review of the

subject. Like all German text-books, this one goes minutely into the pathology of the diseases it describes, and, though very much of it is borrowed, a large part represents Joseph's own investigations. Those only who have studied with him know the capacity and the faithfulness of the author.

The first part of the work deals with syphilis and its many complications. Joseph gives a good prognosis for syphilis if they are kept under constant supervision and upon strict antisyphilitic treatment. And yet he recognizes the difficulties of offering a prognosis in any individual case, and makes the suggestion that the moral as well as the physical care of the patient be a consideration to the physician. He believes in the curability of syphilis, and cites the possibility of reinfection as a proof of it.

Like most syphilographers, Joseph regards the chancre as a specific lesion, but one that never gives rise to constitutional changes. The exact nature of the poison which causes the chancre is unknown. Finger's experiments seem to prove that the site of contagion has much to do with the infection, as to its susceptibility or lack of it; while Köbner's inoculation experiments lead the author to the conclusion that the lesion is caused by a specific micro-organism.

Joseph has not had good results with the Janet treatment in acute gonorrhœa, but says that several cases of chronic gonorrhœa have yielded to this method of injecting potassium permanganate. There is nothing new, or at least nothing strikingly new, in the rest of the chapter on gonorrhœa. The author states in capitals that the gonococcus of Neisser is the etiological factor of blennorrhagic affections.

The book is well printed on heavy paper and is very well illustrated.

*Traité de chirurgie clinique et opératoire.* Publié sous la direction de M. A. LE DENTU, professeur de clinique chirurgicale à la Faculté de médecine de Paris. et M. PIERRE DELBET, professeur agrégé à la Faculté de médecine de Paris, par M. ALBARRAN, M. ARROU, M. J.-W. BINAUD, M. H. BRODIER, M. CAHIER, M. CASTEX, M. A. CHIPAULT, M. J.-L. FAURE, M. M. GANGLOPHE, M. A. GUINARD, M. JABOULAY, M. LEGUEU, M. F. LUBET BARBON, M. C. LYOT, M. P. MAUCLAIRE, M. H. MORESTIN, M. H. NIMIER, M. P. PICHEVIN, M. A. RICARD, M. H. RIEFFEL, E. M. SCHWARTZ, M. P. SEBILEAU, M. CH. SOULIGOUX, M. A. TERTSON, et M. F. VILLAR. Tome premier. Pathologie générale. Maladies de l'appareil tégumentaire. Par M. H. NIMIER, M. A. RICARD, M. J.-L. FAURE, M. A. LE DENTU, M. C. LYOT, M. H. BRODIER, et M. PIERRE DELBET. Avec 64 figures intercalées dans le texte. Paris: J.-B. Baillière et fils, 1896. Pp. viii-823.

This new French system of surgery, if one may judge from the first volume, will be an exhaustive treatise on the subject. The French seem to have regarded the method of "systèmes" as a good one to follow; but even this excellent text-book contains the faults inherent in all works written by different men. The first volume deals with general and special surgical pathology, and, although the editors appear to have tried to harmonize the work, there are many differences of opinion as to the pathology of tumors.

The first part of the book is devoted to confusions and wounds, with an elaborate discussion as to their pathology and a thorough review of their aseptic and

antiseptic treatment. This is followed by a chapter on the complications of wounds, including, first, pain, hæmorrhage, and foreign bodies; second, mental symptoms; third, septic complications. Suppuration, septicæmia, and pyæmia are next considered, and the succeeding chapter deals with the lesions which destroy tissue. A lengthy review of the malignant infectious diseases and of neoplasms concludes the first part of the book. The second portion is devoted to the surgical diseases of the skin. There is nothing new, either in classification or in subject matter, which appeals to the reviewer. The book is wholesome and safe and should certainly prove valuable to the French student and to surgeons in general.

The volume is very well printed on good paper. The illustrations are, as a rule, poor, particularly those of the tumors. German writers are given frequent credit, but Frenchmen can not or will not spell German names correctly.

*Southall's Organic Materia Medica.* Being a Handbook treating of some of the more Important of the Animal and Vegetable Drugs made Use of in Medicine, including the Whole of those contained in the British Pharmacopœia. Designed for the Use of Teachers, Pharmaceutical and Medical Students, Chemists, Druggists, and Others. Fifth and Enlarged Edition by JOHN BARCLAY, B. Sc. Lond., Sometime Lecturer on Materia Medica and Pharmacy in Mason College, Birmingham. London: J. & A. Churchill, 1896. Pp. xix-307. [Price, \$2.10.]

Those who wish a small work in which the organic materia medica is considered from the botanical standpoint and is treated rather for pharmaceutical purposes than for physicians, may wisely possess themselves of this book. It is not adapted to the use of medical men as we view that use, for of the medicinal application of remedies it contains but the briefest utterances; but chemically and botanically important matters are well though briefly presented, and the arrangement of the book is such as to make its contents readily available. It conforms to the British Pharmacopœia, however, which fact will, in spite of its advantages to the pharmacist, militate much against its usefulness in this country.

*A Handbook of Pathological Anatomy and Histology.* With an Introductory Section on Post-mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By FRANCIS DELAFIELD, M.D., LL.D., Professor of the Practice of Medicine, College of Physicians and Surgeons, New York, etc., and T. MITCHELL PRUDDEN, M.D., Professor of Pathology and Director of the Laboratories of Histology, Pathology, and Bacteriology, College of Physicians and Surgeons, New York. Fifth Edition. Illustrated by Three Hundred and Sixty-five Wood Engravings printed in black and Colors. New York: William Wood & Co., 1896. Pp. viii-3 to 846.

The fifth edition of this well-known work shows that the object, the aim, and the character of its immediate predecessor remain unchanged. That the revision has been well and satisfactorily done, it is scarcely necessary to say, and by consideration of the recent additions to pathological knowledge the work ably maintains and continues the value possessed by the former

editions. The addition of a number of very excellent illustrations contributes largely to the greater usefulness of the recent edition, and the work remains one of the best upon the subject of which it treats, for, above all things, it is practical.

*A Text-book of Diseases of the Nose and Throat.* By FRANKCE HUNTINGTON BOSWORTH, A. B. Cantab., A. M., M. D., Professor of Diseases of the Throat in Bellevue Hospital Medical College, New York, etc. Illustrated with One Hundred and Eighty-six Engravings. New York: William Wood and Company, 1896. Pp. xix-3 to 814.

DR. BOSWORTH'S work on the nose and throat, in two volumes, is doubtless known to the majority of our readers, and the work now under consideration therefore needs little save mention, for, as the preface says, it is mainly a condensation of the author's former two volumes into one, in which the effort has been to retain all that is of practical use so far as possible. This, he says, has been accomplished by eliminating those parts of the work which were of value only for reference, and he trusts that it has been done to the satisfaction of the reader. Some new material has been added, and some few changes have been made, but in essentials, he adds, the single volume is the same as the larger edition.

It would be a carping reader, indeed, to whose satisfaction the work had not been done, for to our mind the single volume presents many advantages over its two-volume predecessor. No doubt the specialist may prefer the latter, though he is not likely to complain of insufficiency in the former, but to the general practitioner the single volume is far more suited, and by him will be far more highly appreciated. The student of medicine, too, will find this work more available than the former edition, though for him we think even the single volume is somewhat too plethoric. We think, therefore, that the work has its most useful field among general practitioners, and to these it can be most warmly commended.

*A Manual of Materia Medica and Pharmacology.* Comprising all Organic and Inorganic Drugs which are and have been Official in the United States Pharmacopœia, together with Important Allied Species and Useful Synthetics. Especially Designed for Students of Pharmacy and Medicine, as well as for Druggists, Pharmacists, and Physicians. By DAVID M. R. CULBRETH, Ph. G., M. D., Professor of Botany, Materia Medica, and Pharmacognosy in the Maryland College of Pharmacy. With Four Hundred and Forty-five Illustrations. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. xi-17 to 818. [Price, \$4.75.]

THAT this work will unquestionably be of service to students of pharmacy and to the pharmacists is not to be denied, for it is an able and thorough consideration of the materia medica, both official and unofficial, studied from the botanical and pharmaceutical standpoint. That it will be of any service to medical men, students or practitioners, is improbable, to say the least, for its therapeutics is scanty, and botany and pharmacy, the very things which medical teachers most wisely minimize, are here made pre-eminent. The medical student of the present day has far too much that is vital to learn to waste time upon the unnecessary, but, notwithstanding his overburdened condition, enthusiastic spe-

cialists would add to his information (and his burdens) by treatises "designed for the use of medical students" which they fondly think are suited to his needs, whether they are or are not. Botany and pharmacy are prominent among the subjects which are not, a fact which medical teachers generally recognize, and which some day pharmaceutical teachers will come to learn.

Although we fail to see the utility of this work in the case of the medical man, save possibly as a work for occasional reference, we must value it highly for the use of the pharmaceutical student, for whom its completeness and its well-ordered arrangement will certainly render it valuable.

#### BOOKS, ETC., RECEIVED.

*Human Anatomy. General and Descriptive. For the Use of Students.* By John Cleland, M. D., LL. D., D. Sc., F. R. S., Professor of Anatomy in the University of Glasgow, and John Yule Mackay, M. D., C. M., Professor of Anatomy in University College, Dundee, etc. With Six Hundred and Thirty Illustrations, of which Two Hundred and Fifty-seven by the Authors are now Printed for the First Time. New York and London: The Macmillan Company, 1896. Pp. xx-833. [Price, \$6.50.]

*A Treatise on Surgery.* By American Authors. For Students and Practitioners of Surgery and Medicine. Edited by Roswell Park, A. M., M. D., Professor of the Principles and Practice of Surgery and of Clinical Surgery in the Medical Department of the University of Buffalo, etc. Volume II. Special or Regional Surgery. With Four Hundred and Fifty-one Engravings and Seventeen Full-page Plates in Colors and Monochrome. Philadelphia and New York: Lea Brothers & Co., 1896. Pp. 7 to 804.

*The Surgery of the Chest.* By Stephen Paget, M. A. Oxon., F. R. C. S., Surgeon to the West London Hospital, etc. Illustrated. New York: E. B. Treat. Bristol: John Wright & Co. Montreal: J. Hood Company, 1896. Pp. x-479.

*Skiascopy and its Practical Application to the Study of Refraction.* By Edward Jackson, A. M., M. D., Professor of Diseases of the Eye in the Philadelphia Polytechnic and College for Graduates in Medicine, etc. Second Edition. With Twenty-seven Illustrations. Philadelphia: The Edwards & Docker Company, 1896. Pp. 7 to 108.

*Transactions of the American Climatological Association.* For the Year 1896. Volume XII, containing Part II of the Report of the Committee on Health Resorts.

*The Treatment of Habitual Constipation.* By Max Einhorn, M. D. [Reprinted from the *Post-Graduate*.]

*Enteroptosis.* By Max Einhorn, M. D. [Reprinted from the *Medical News*.]

*On Functional Disorders of the Stomach accompanied with Hypersecretion.* By Max Einhorn, M. D. [Reprinted from the *Medical Record*.]

*Intestinal Obstruction after Laparotomy.* By Henry O. Marcy, M. D., of Boston. [Reprinted from the *Journal of the American Medical Association*.]

*The Want of College Instruction in Electrotherapeutics.* By Robert Newman, M. D. [Reprinted from the *Electrical Journal*.]

*The Surgical Treatment of Hemorrhoids by Excision and Closure with the Buried Animal Suture.* By Henry O. Marcy, M. D. [Reprinted from the *American Journal of Obstetrics*.]

Clinical Notes on Methods and New Remedies in the Treatment of Diseases of the Upper Air Passages. By Walter F. Chappell, M. D. [Reprinted from the *Canada Lancet*.]

De l'emploi de l'ichthyol dans le traitement de la tuberculose pulmonaire. Par le Dr. Maurice Le Tanneur, Médecin de l'hôpital dispensaire de Belleville. [Extrait du *Journal de médecine de Paris*.]

## Reports on the Progress of Medicine.

### OTOLOGY.

By CHARLES STEDMAN BULL, M. D.

**Antiseptic Treatment of Simple Chronic Suppuration of the Tympanic Cavity; Systematic Tamponing of the External Auditory Canal with Iodoform Gauze.**—Fongery (Ann. des mal. de l'oreille et du larynx, June, 1895) draws the following conclusions from his observations:

1. The external auditory canal is a channel by which the middle ear often becomes infected by penetration of staphylococci into the tympanic cavity.

2. The use of non-sterilized cotton tampons has been known to cause secondary infection. The method of exposure to the flame of alcohol saturated with boric acid is very simple and should be always employed.

3. To avoid the spread of secondary infection from non-sterilized cotton or dirty cotton, the external auditory canal should always be tamponed by iodoform gauze. This method is very simple, antiseptic, easy of application, arrests all germs contained in the air, and is well borne by the patients.

**The Treatment of Cholesteatoma of the Petrous Bone with a Permanent Retro-auricular Opening.**—Reinhard (Arch. of Otol., xxiv, 2) believes that the only way of bringing about a permanent cure in these cases is to produce a permanent opening toward the external meatus as well as in the lateral wall. This is to be accomplished in one of three ways: 1. By implantation of broad-based cutaneous flaps from the scalp by Schwartz's method. 2. By Thiersch's transplantations. 3. By cutaneous flaps from the posterior surface of the concha. This prevents the subsequent growth of hair into the cavity. The cutaneous flap should be formed at the beginning of the operation by cutaneous incisions down to the cartilage, one centimetre behind the external margin of the concha; then dissect the flap up to the mastoid process, placing its largest side upon the upper angle of the wound; and finally make the typical parallel incision behind the concha down to the periosteum. The cutaneous defect of the concha may be covered by Thiersch's transplantations.

**The Evils of Wilde's Incision.**—Chippault and Demoulin (Ann. of Ophth. and Otol., iv, 4; also Ann. des mal. de l'oreille et du larynx) think that Wilde's incision has no advantages, and causes the loss of valuable time. If there is really pus in the mastoid cells, the external incision does little good. It is only useful in cases of simple periostitis. In cases of purulent mastoiditis the incision is not reasonable, because it does not attack the seat of the trouble, but merely relieves the one symptom of pain.

**Ethmoiditis Suppurativa, Acuta and Chronica; Cause, Diagnosis, and Treatment.**—Farber (Ann. of Ophth. and

Otol., January, 1896) regards this disease as of common occurrence, and the result of acute rhinitis which has extended through the anterior ethmoidal cells to the frontal sinuses. There is a history in all cases of one or several attacks of inflammation of the frontal sinuses, severe frontal headache, chill, fever, etc. Many cases of this character go on to complete resolution and cure; many more end in the chronic form. The treatment for the acute cases, which should be rigidly carried out, should be confinement to the house for eight or ten days, purgation, hot foot-baths, opium, belladonna, acornite, and quinine.

The symptoms of chronic anterior ethmoiditis are frequent headaches and the presence of a thick, almost purulent discharge, and a large, tough scab coming from one side of the nose, with a more or less catarrhal condition of the nasopharynx. The discharge and the peculiar scab are diagnostic. The latter is found on the middle turbinate near its anterior extremity, extending over to the septum, and completely blocking the superior meatus. The secretion is soft, slightly tenacious, and greenish-white in color. On its under side it is hard and dry, brownish-yellow, deeply concave, and holds its shape when discharged. The pus, dripping from above, gradually fills the superior meatus and runs back to the nasopharynx. There is practically no odor perceptible to others, but the patient himself is conscious of a slight stench.

The treatment consists first in remedying the existing hypertrophies, keeping the nares clean, and opening up the anteriorethmoidal cells through the infundibulum. The anterior end of the middle turbinate should be cut off with a small bone forceps, so as to prevent the accumulation of secretion and give drainage. The infundibulum must then be opened by the dentist's drill, and its direction, starting from the level of the amputated middle turbinate, should be backward, upward, and outward toward the anterior ethmoidal foramen. The structure is easily penetrated, and the pain is not great, and may be alleviated by cocaine. Two or three openings will be sufficient. The size of the "burr" should be about an eighth of an inch, and it should penetrate from a quarter to half an inch, or until the drill has penetrated a cell. Hæmorrhage is not excessive, but is more or less oozing and constant, and therefore it is better to pack the nose. The openings should then be flushed with sublimate solution (1 to 4,000) or with hydrogen peroxide. The edges of the openings should be cauterized with the galvanocautery.

**The Paracausis of Willis.**—D'Aguanno (Ann. des mal. de l'oreille et du larynx, February, 1896) concludes from his observations that paradoxal deafness is a phenomenon which is symptomatic either of torpor of the auditory nerve or flexion of the drum cavity. The tympanic affection which occasions it may be due either to an interruption in the chain of bones, or to a relaxation of the ligaments of the ossicles, or to degeneration of the intratympanic muscles.

**The Importance of the Cochlea and its Different Segments for the Function of Audition.**—Corradi (Ann. des mal. de l'oreille et du larynx, April, 1896) draws the following conclusions from his experiments: 1. It is probably true that the cochlea is the organ of acoustic sensations. After the bilateral destruction of this organ in guinea-pigs, the latter become absolutely deaf. 2. If those portions of the internal wall of the drum cavity round the base of the cochlea be destroyed, while the

latter is left intact, the hearing is maintained. 3. The hearing for different tones, from highest to lowest, is uniform in all the segments of the cochlea. If, on destroying the upper part of the cochlea in guinea-pigs, the acoustic reaction for low and middle tones disappears, while it may be preserved for high tones, this reaction for low and middle tones is much more manifest. It is therefore natural that this reaction for low and middle tones, which is feeble in the normal state, should be completely wanting in the operated animal. This opinion is confirmed by the fact that in attacking the summit of the cochlea the acoustic reaction ceases sometimes even for certain extremely high tones and may be maintained for low tones, and that the reaction for high tones may persist of injury to the base of the cochlea.

**The Hearing Power in Cases of Bilateral Congenital Atresia of the Auditory Canal with Rudimentary Auricle.**—Bezold (*Arch. of Otol.*, xxv, 2) thinks that in these cases the disturbance is limited to the external and middle ear, and affects particularly the annulus tympanicus, which is mostly wanting; then the malleus and incus, which are absent or rudimentary, and, as a rule, also, the stapes. The hearing power in these cases may be considered that of an intact labyrinth shut off from the action of aerial waves of sound, and with disturbances in the conducting chain. The abnormalities in the conducting apparatus, in cases of congenital atresia, are so manifold that they can not be brought into a single category. It must be left an open question whether there can be any hearing when the tympanum is entirely absent. It must also remain doubtful whether there can be any hearing when one or both labyrinth windows are congenitally absent. In grouping together the results of auditory tests in these cases, we find (1) a lengthening of the normal time for bone conduction, (2) a marked negative Rinné, and (3) a defect for low tones by bone conduction.

**Some of the Peculiarities of the Negro in Otolgy.**—Roaldes (*Rev. de laryngol. et d'otol.*, December 15, 1895) notes that in the negro the concha is smaller and more fleshy than in the white. The outlines of elevations and depressions of the anterior surface are less graceful. The concha is more closely applied to the skull than in the white. The external auditory canal is more developed and spacious and much straighter in the negro. The mastoid apophysis is less developed, the cortical portion is harder and thicker, and the antrum is less spacious in the negro. The nasopharynx is very much more spacious, the mouths of the Eustachian tubes are much larger in the negro, and the septum nasi is much straighter and more regular than in the white.

The negro is much less prone to eczema of the auricle and canal, but is more liable to cheloid degeneration than the white. Deafness of all kinds is much less common in the negro, and this is also true as regards deaf-mutism.

**Cavernous Angioma of the Ear.**—Moure (*Rev. de laryngol. et d'otol.*, December, 1895) reports a case of this kind occurring in a woman aged forty-seven years. At the entrance of the external auditory canal was a deep-red tumor, like a grain of wheat, and below it a smooth, grayish-pink globular tumor, which leaned to the superior or postero-superior wall of the drum cavity. It was surrounded by pus. The tumor was removed by the snare, and this was immediately followed by a large quantity of black blood. This flow was eventually arrested by tampons of borated cotton, and later

by iodoform gauze. This was followed by considerable swelling and rise in temperature, so that on the fourth day part of the gauze tampon was removed. The microscope proved the tumor to be a fibro-angioma.

**The Role of Staphylococci in Otorrhœa.**—Lermoyez and Helme (*Ann. des mal. de l'oreille et du larynx*, July, 1895) draw the following conclusions from their observations: 1. The *Staphylococcus pyogenes*, rare in the beginning of purulent otitis, becomes very frequent as the otorrhœa becomes chronic. 2. Their tardy appearance is the result of a secondary infection which has been experimentally demonstrated. 3. There is no proof that they do not come from the external auditory canal, but, on the contrary, both clinical and experimental facts prove their tardy arrival by this channel. 4. Extemporaneous sterilization by means of the flame of borated alcohol is the simplest method of protecting the ear from secondary invasion.

**The Disturbances of Equilibrium in Diseases of the Ear.**—Von Stein (*Arch. of Otol.*, xxv, 1) states that disturbances of co-ordination may occur in ear diseases:

1. With the eyes closed (in the absence of ataxy and alterations of sensibility).
2. With the eyes open, the rapid movements never attain their normal correctness and promptitude, but are often doubtful and slow.
3. They may be only observed in certain situations and directions.
4. They are not always equally divided between the two lower extremities.
5. There is polymorphia in the disturbances.
6. Easy weariness, especially with closed eyes.
7. A smaller angle of inclination on the goniometer.
8. With simultaneous diminution of hearing or another disease of the ear.
9. Tinnitus or loss of hearing.
10. With some nasal diseases, as adenoids and hypertrophic rhinitis.
11. Attacks of vertigo, with exclusion of nervous and ocular disease.
12. The patient, on falling, retains his consciousness.

From a prognostic point of view, the more marked, permanent, or manifold the disturbances of equilibrium in a peripheral disease of the ears, with simultaneous loss of hearing, the less hope there is of any restoration of hearing.

**The Treatment of Intracranial Abscesses following Purulent Diseases of the Ear.**—Barr (*Arch. of Otol.*, xxiv, 3 and 4) suggests the following subjects for full discussion:

1. It is desirable that the pure otologist should himself operate on the skull and brain in these intracranial complications of ear disease.
2. Should the interior of the cranium be opened, even when the symptoms point to diffuse meningitis?
3. What is the best method of dealing with a thrombosed lateral sinus? Ligating the jugular vein, or incision and pressure?
4. What is the best method of perforating the bone while opening the cavities of the middle ear, or the cranial septa of the middle ear?
5. The value of operative treatment on the cavities of the middle ear for the cure of intractable purulent cases, as preventive of intracranial abscesses.

**The Aura of Auricular Vertigo.**—Gellé (*Ann. des mal. de l'oreille et du larynx*, March, 1896) concludes that the sensory or motor phenomena premonitory of an

attack of auricular vertigo clearly show that the irritations of the auditory nerve in man produce not only the diverse perturbations of the equilibrium and of movements which we see in experiments in the laboratory, but that they also act on the psychic centres, and provoke the appearance of actual hallucinations of the senses and of movements.

**An Otolological Basin.**—Alderton (*Ann. of Ophth. and Otol.*, iv, 4) has devised an aid to cleanliness in the treatment of the ear, which consists of an ordinary hard-rubber *papier-maché* or metallic pus basin of any of the common shapes. To this a metallic tube, five inches long by an inch in diameter, is cemented or riveted perpendicularly to the middle of the bottom of the basin, after cutting out a button an inch in diameter at the point of application. In use a soft-rubber tube an inch in diameter is drawn over the free extremity of the tube in such manner as to form a continuation of it. This rubber tube may pass through a screw-eye let into the edge of the operating table, and so down into any large receptacle on the floor. The patient holds the basin by the metallic tube; the basin is placed in position, and all fluids, during syringing or dressing, pass uninterruptedly down the tubes into the receptacle under the table, while the gauze and other solid dressings remain in the basin and gradually drain dry.

**Systematic Acoustic Gymnastics in the Treatment of Deaf-mutism and Cases of Nerve Deafness in General.** **The System of Urbantschitsch.**—Barnes (*Ann. of Ophth. and Otol.*, iv, 3) describes Urbantschitsch's method as virtually a vocal training of the auditory nerve whereby a gradual irritability of the nerve for sound waves is set up. Instruction begins with the vowels. Two are selected, usually A and O, as they are the most readily understood. The one to be used is first indicated to the patient by the lips, and then in a loud and prolonged voice is spoken directly into the ear. The patient in the beginning may not hear a sound, but persistent and continued effort will, even sometimes at the first sitting, enable him to arrive at a distinction. As soon as this distinction of the vowels is mastered, consonants are added to them, gradually increasing to long syllables, then to words, and finally to complete sentences. As progress is made, the distance from the ear at which the exercise is conducted may also be gradually increased, and after a few sittings it is best to dispense with the lip method, making the exercise purely acoustic. While perception of sound is essentially necessary to gaining any progress in a case, *conception* of sound makes the *perception* easier. It is much easier for a deaf-mute to reproduce a sound that conveyed some intelligence to his mind than one that did not. Short, continued practising of from five to ten minutes gives the best results. It should be daily at first, gradually increasing in frequency rather than lengthening the duration. The pitch and intensity of the voice suited to the case must be determined, and great care taken that the irritability of the nerve be not exhausted. Should this occur, all practice must be stopped for a few days.

The results to be obtained depend largely upon the systematic manner in which the exercise is conducted, but there must be, in the first place, an existing ability to hear, and an ability for development of the hearing. The same method is applicable to cases of acquired deafness resulting from scarlet fever, typhoid fever, cerebro-spinal meningitis, diphtheria, measles, etc.; for it is of utility not alone for the nerve, but also for the long-standing obstructive sequelæ.

**An Unusual Case of Aural Deformity.**—Holinger (*Ann. of Ophth. and Otol.*, iv, 2) reports an interesting case occurring in a girl aged fourteen years. The whole head was asymmetric. The left facial side was inferior to the right in all dimensions, and showed a marked depression which extended from the ramus of the lower jaw to the linea temporalis, and from the zygoma to the occipital region. The lobule of the ear was smaller than normal, but it seemed as if the superior point of insertion of the concha had been drawn downward and forward toward the external angle of the mouth. The line of insertion formed three quarters of a circle, and the free margin of the concha was bent upon itself forward and at an acute angle. The tragus was absent. In operating for the correction of the deformity half the concha was dissected from its broad and flat attachment to the cheek and sewed to an incision in the vertical prolongation of the still adherent part. The force necessary to bring together by stitches the original insertion, two centimetres broad, caused the incision to gape sufficiently, and enabled us to avoid sacrificing any skin at the posterior incision, although the wound in the cartilage on the posterior surface was a centimetre and a half broad. At the same time the strong tendency of the concha to dip forward could be combated in a fashion similar to that adopted in operations on fan-ears. A slight ectropion was produced which soon disappeared.

**Micro-organisms in the Healthy Nose.**—Thomson and Hewlett (*Arch. of Otol.*, xiv, 3 and 4) summarize the results of their observations as follows:

1. In all bacterioscopic investigations of the nasal fosse, in all researches as to the action of nasal mucus, etc., a clear distinction must be made between the vestibule of the nose and the proper mucous cavity. The former is lined with skin, and is not part of the nose cavity proper, but only leads to it.

2. Contamination with the lining of the vestibule is difficult to avoid, even when this source of error has been realized.

3. In the dust and crusts of mucus and *débris* deposited among the vibrissæ of healthy subjects micro-organisms are never absent, and are usually abundant.

4. On the Schneiderian membrane the reverse is the case. Under normal conditions micro-organisms are never plentiful here, are rarely even numerous, and in more than eighty per cent. of cases no organisms whatever are found, and the mucus is completely sterile.

5. The occurrence of pathogenic organisms must be so infrequent that their presence on the Schneiderian membrane can only be regarded as quite exceptional.

**Binaural Hearing.**—Bloch (*Arch. of Otol.*, xxiv, 2) sums up the characteristics of binaural hearing as follows:

1. With binaural conduction of a sound there is an alternating increase in the auditory impression.

2. This increase grows less as the two auditory impressions become more dissimilar.

3. It depends probably not only on the addition of the bilateral acoustic excitation and the transference of the perception to the interior of the head, but also on an actual central increase of excitability.

4. With the binaural conduction of a tone or a noise into the auditory canal, or in its neighborhood, the sound is heard in the head.

5. The subjective auditory field lies on the side of the stronger perception. By changing this, the location of the field may be altered at will.

6. Its location in the median plane, and the perception of the character of the tone, depend on the relations between the phases of the sound waves on each side.

7. The most important function of binaural hearing is the recognition of the direction of sound.

8. This is more perfect in the horizontal and frontal planes than in the sagittal.

9. In the two former it depends chiefly upon the comparison of the intensity of the sound perception on both sides, and in less measure on the influence of the auricle on the conduction of the sound waves to the canals.

10. In the sagittal plane the last factor alone comes into play.

11. Different characteristics of the sound, such as its duration, intensity, and timbre, influence our judgment of the direction, particularly in the sagittal plane, corresponding to the more frequent excitation of the auditory nerves, and the repeated experiences of daily life.

12. In the estimation of the distance of a sound, we judge less from the total intensity than from the intensity of the component single sounds.

13. The judgment of the direction of sound with one ear alone is very poor.

14. It does not seem necessary, in judging of the direction of sound, to take into account any other than the physiological and psychological factors here discussed.

**Some Tumors of the Ear.**—Scheibe (*Arch. of Otol.*, xxiv, 3 and 4) reports three interesting varieties of aural tumors:

The first was a fibroma, at the entrance of the ear canal, occurring in a man aged fifty-six years, which had been growing for six years. It was club-shaped, rather hard, the size of a small walnut, covered by skin partially supplied with hair and glands. It was removed by the galvano-cautery snare. It proved to be a fibroma of the subepithelial connective tissue, with proliferation of sebaceous glands. There had been no relapse in seven years.

The second was a pedunculated osteosarcoma of the ear canal in a young lad aged seventeen years. There had been impairment of hearing for a week, and an offensive discharge for four days. The osseous meatus was filled with a hard tumor with irregular excoriated surface, connected with the bone at the anterior wall. After the removal of the thick fibrinous outer coat the growth appeared as a deep-red, shining, lobulated tumor, oval in shape, as large as a bean, and was attached by a small pedicle to the supero-anterior wall of the meatus. It was removed with a snare. The decalcified tumor was divided by a longitudinal incision passing through the pedicle. One half was cut into longitudinal sections and the other into vertical sections. It proved to be a combination tumor, the bulk being sarcoma tissue pervaded with osseous trabeculae extending from the pedicle to its centre. The sarcoma portion was rich in spindle-shaped cells with some giant cells. The pedicle of the tumor consisted of well-developed bone, from which many spiculae radiated through the tumor. A thick epidermic stratum covered the tumor.

The third variety of tumor consisted of three cases of hairy granulation tumor in the middle ear. The first case occurred in a man, aged forty-one years, who had suffered from left otorrhea from childhood. A tumor had been removed five times from this ear, the

last time three years before, since which the ear had been dry. A pedunculated, soft, uneven tumor was found filling the bottom of the meatus, and the pedicle was in the antrum canal. When removed with the snare its surface was found studded with stout hairs. The drum membrane and ossicles were absent. A part of the posterior wall of the bony meatus was destroyed. The whole cavity of the drum was lined with horny epidermis. Three years later the tumor recurred, and on being removed was found covered with hairs, which were growing from hair follicles.

The third case occurred in a man, aged twenty-four years, who had had an intermittent discharge from one ear for fourteen years. The drum membrane and malleus were absent. The tympanic cavity was lined by thick white epidermis. A large mass of cholesteatoma was removed, and a pale red polypus was snared off. This, on examination, proved to be a mass of connective tissue, sebaceous glands, hair follicles, and glands.

In both these patients the tumor grew on the soil of a cholesteatoma, but this does not explain the development of the hairs.

## Miscellany.

**Thyroid Extract in the Treatment of Lupus.**—In the *British Medical Journal* for October 24th Dr. J. Barclay calls attention to the results obtained by him in the treatment of lupus by thyroid extract. The slight extent of his experience with thyroid in the treatment of lupus does not, he thinks, entitle him to be dogmatic as to results, but the progress of the cases has been watched with considerable care during the whole course of the treatment, in order to render any conclusions arrived at as trustworthy as possible. Dr. Barclay relates the histories of four cases, of which the following are examples:

The first patient was an unmarried woman, aged twenty-five years, who had been the subject of lupus of the nose and both cheeks since 1891. Scraping had been thoroughly done in 1892, and, on the disease returning, scraping and Paquelin's cautery were employed in 1893. Relapse soon followed, and in January, 1895, thyroid tablets, one three times a day, were given. In three weeks local reaction became apparent, very markedly resembling that following Koch's tuberculin in this disease. First there appeared a bright-red ring surrounding each nodule, with swelling of the nodule and tenderness, indicating acute inflammation. The dose was now increased to six tablets daily, and after a couple of weeks nine were taken. These were well borne, nothing worse than emaciation being observed during the months of the treatment. This condition of inflammation persisted for several weeks, at the end of which the nodules began to soften and break down. Complete sloughing followed, and a deep ulcer took the place of the nodules. At this stage all the surrounding redness had disappeared. After all the nodules had pursued this course of inflammation and consequent necrosis, the parts previously affected presented a series of clean and healthy looking sores, from which a thin discharge exuded. Healing was slow. Yet by merely keeping the parts clean by washing with soap and water, and by covering with vaseline to prevent the formation

of scabs, healing was gradually accomplished, and there remained only a white, flat, and sound scar. No other external application than vaseline was employed. Dr. Barclay regrets that the discharge from the ulcers was not examined for bacilli, and that no note of the temperature during the stage of inflammation of the nodules was kept. In September, 1895, it was noted that the face was nearly well, and in January, 1896, quite well. At this date—July 16, 1896—the face remains quite well.

In another case the patient was a married woman, aged thirty-five years. She had been the subject of extensive lupus of the face since 1889. The disease included a large patch on the right cheek, one on the upper lip, and the whole of the nose and interior of the nostrils. Various attempts at destruction of the malady had been made before the author saw her, which was in April, 1891. At that time a thorough scraping was done, but the disease returned more actively than before. Cod-liver oil was taken from that time to the end of 1892, but without apparent benefit. In February, 1893, scraping and Paquelin's cautery were followed by temporary benefit, but after a few months matters were as bad as before. In January, 1895, thyroid tabloids were ordered, but were taken very irregularly, and sometimes ceased to be taken altogether for weeks at a time during all that year. On all the occasions on which the medicine had been continuously taken for three or four weeks, the usual local reaction, which is described as having occurred in the preceding case, was observed—namely, redness, swelling, and pain; but immediately on leaving it off these local signs gradually died away, and no necrosis or sloughing of the nodules followed. However, in January of this year the patient took the tabloids in earnest, first three daily, after a fortnight six, and after a month nine a day. The result at this time is that the whole of the nodules on the nose have sloughed away, and the deep ulcers left have become filled up, and cicatrization is going on steadily. The patch on the right cheek, which had somewhat healed over before the thyroid treatment was begun, has become inflamed, but no necrosis has followed. The nodules on the upper lip, which all along were larger than those on the nose, seem to have been more slowly affected by the thyroid than the others, and at this time all have not softened down *pari passu* with their neighbors. She continues to take the medicine steadily. The only external application employed is vaseline.

The whole process of the local reaction following thyroid treatment, says Dr. Barclay, is very similar to that which we were accustomed to observe after tuberculin injection, with this difference, that the thyroid reaction is less violent, both locally and constitutionally, and the good effects will, he trusts, be more complete and more permanent. Mr. Jonathan Hutchinson in February, 1891, speaking of the treatment of lupus by Koch's method, remarked: "No one ventures to report an instance of complete cure. Of the cases which have been shown to me as the most satisfactory, I am bound to say that in every one there has been evidence at some part of the edge of the remains of lupus tissue ready, I do not doubt, to start into fresh growth on the slightest provocation." Time and experience, continues the author, have shown the truth of this statement. Judging from these two cases there is in them no such suspicious appearance up to the present time. As to the duration of the treatment necessary to insure per-

manent cure, even with full doses given regularly and continuously, it would seem as if one could not trust to a complete cure being effected in a shorter time than a year. The dose of the medicine in lupus, as in psoriasis, requires to be larger than what is found sufficient for myxodema. And, as regards the age of the patient, the older he or she may be, the more cautious ought we to be with the quantity prescribed. Dr. Barclay states that he has observed no serious effect in youthful patients, but in those who have passed fifty years of age some irregularity of the heart's action has been noticed, which is controlled easily, however, by reducing the dose and giving some alcoholic stimulant. Some interesting questions, he thinks, might arise in the course of this treatment. For instance, he asks, would it not be prudent during the necrotic stage of the nodules periodically to examine the discharge for bacilli? Valuable information as to the progress of the treatment might thereby be obtained. Then one might ask what would be the effect of a similar treatment in tuberculous glands in the various situations in which these are found? Would it be analogous to what he has described in lupus? And, lastly, what would be the probable effect of this treatment in tubercle of the lungs?

#### Antipyrine in the Treatment of Whooping-cough.—

In the *Gazette hebdomadaire de médecine et de chirurgie* for October 22d M. Le Goff calls attention to the results obtained by many authors with this treatment. Dubousquet-Laborde employed it in three hundred cases, in which a hundred and ninety-six patients were cured or benefited. The average duration of the treatment was thirty-five days. The amounts given daily varied from five to fifteen grains for children up to three years of age, and from thirty to sixty grains for older children and adults. The same results were observed by Geffrier, De la Jarrige, Jasiewicz, and others. Richardière also employed antipyrine with satisfactory results. It diminished the number of coughing attacks one third in the majority of cases, although it never suppressed them completely. In two cases in which the patients vomited profusely it had no effect on the vomiting. He concluded, however, that antipyrine exerted a positive action, but that it was not superior to that of belladonna.

Whenever the renal functions are not impaired, says the author, M. Lemoine prefers this medication to any other, as its action is surer and more rapid. To small children he gives from four to eight grains in enemata every twenty-four hours, and to children from three to six years of age and older, twenty-four grains in six doses.

Von Genser enumerated the results obtained by him in two hundred cases, in which he employed two methods of treatment: Insufflations of powdered medicaments into the nasal fossæ and antipyrine administered by the stomach. With the first method few results were obtained, and the duration of the treatment was at least forty-three days; in the second the results were more conclusive. Administered in quantities of two grains a day for each year of the child's age, antipyrine always diminished the number of coughing attacks and lessened their violence. Recovery was obtained in twenty-four days, and from this the author concluded that antipyrine shortened the duration of the disease. Many other instances are cited by M. Le Goff to demonstrate the efficacy of this treatment.

In regard to its mode of action, he says, the drug

is essentially a nerveine, and acts as an analgetic and as an antispasmodic. By diminishing the irritability of the superior laryngeal nerve which, by reflex, produces the cough, it arrests the attacks of coughing and prevents serious symptoms which the intensity of the attack may cause. This action on the nervous element of the cough is the least disputed of the effects of antipyrine in whooping-cough, and was observed by M. Le Goff himself in eighteen patients, in seventeen of whom the number of attacks and their intensity diminished considerably, and in nine recovery occurred in less than twenty-five days, thus cutting short the duration of the disease very much.

In the second place, antipyrine is an antiseptic. Brouardel and Loye have shown that it is antizymotic. A five-per-cent. solution hinders the development of microbes and attenuates their virulence; furthermore, its action has been manifested as well in laboratory experiments.

Concerning its action on the catarrhal element of this disease, says the author, Mouvet affirmed that, if it was given in the first stage of the affection, it arrested the catarrh; Soula also observed similar results. M. Le Goff himself administered antipyrine to a patient during the first stage of the disease, and not only the attacks of coughing, but the catarrh disappeared in seven days. In his other patients he remarked that the catarrh disappeared under the influence of this treatment more rapidly than is ordinarily the case after the cessation of the attacks, and on this point he is corroborated by other observers.

M. Le Goff states that the only symptom he has observed to follow the use of antipyrine is albuminuria, which appeared in two cases; it disappeared, however, rapidly after the cessation of the use of the drug and the establishment of a milk diet. Concerning its elimination, he says, many physiological experiments and the majority of clinical observations demonstrate that it is eliminated well in animals and in persons with healthy kidneys; children, particularly, eliminate it easily. It has been said that antipyrine causes various eruptions, but they are not always followed by injurious consequences, and they disappear after the suspension of the drug. Cordes, Taylor, Dubousquet-Laborderie, and others, cite instances to show that it causes nausea, vomiting with epigastric pains, and anorexia. It is not known, says M. Le Goff, whether these symptoms are to be imputed to any impurities in the drug, to an excess of action, or to peculiar individual susceptibilities. M. Dubousquet-Laborderie thinks that the former play a certain part in giving rise to the symptoms observed. However, says M. Le Goff, the benignity of these symptoms is sufficiently assured, and we need not fear to give antipyrine even in large doses. It is prudent, however, to watch the elimination carefully, and before giving the drug to ascertain the condition of the renal filter.

In order to prevent any injurious action on the digestive tract, the drug is given in Vichy water as follows:

R Antipyrine.....	15 grains;
Gooseberry syrup.....	300
Vichy water.....	2.5 ounces.

M. This quantity is to be taken in twenty-four hours, a dessertspoonful after each coughing attack. Besides this, M. Le Goff recommends the ingestion of milk or bouillon after each dose of the solution, as the antipyrine is thus very well tolerated.

**Influenza in its Connection with Pregnancy and Confinement.**—In the *Journal des praticiens* for October 24th M. Demelin calls attention to the influence of this disease on pregnancy. It was observed, he says, by Valesco de Tarente in the fifteenth century and afterward by Paré, Guillemeau, Mauriceau, Peu, Dionis, Levret, and de la Motte. At the present time certain authors think that abortion is not more frequent from influenza than from any other cause; on the other hand, the disease is distinctly accused of producing premature confinement by Labadie-Legrave, Gottschalk, Queirel, and others. Ruffié concludes that grippé influences pregnancy in nearly the same proportion as cholera, small-pox, typhoid fever, and malarial fever; abortion is produced in forty-one per cent. of the cases and premature confinement in twenty-seven per cent. Séguel, who thought that Ruffié's statistics were overdrawn, nevertheless conceded that *la grippé* was a real cause of abortion.

The cough, the hyperpyrexia, the hæmorrhage from congestion of the endometrium, and the placental apoplexy, the infection properly so called, have been, says M. Demelin, by turns considered as direct agents of uterine evacuation. In a large number of cases pregnancy continues for the normal period, and at the time of confinement the uterine contractions seem generally to be less energetic and occur at longer intervals, which prolongs the duration of the confinement.

Peu, Jacquemier, Cazeaux, and others, have spoken of rupture of the membranes under the influence of the cough. This rupture may occur prematurely, before the beginning of confinement, during the period of dilatation, or at the moment of complete dilatation.

It is especially after confinement that it is important to recognize this disease and to distinguish it from ordinary puerperal infection. Headache, slight chills, fever, collapse, obstruction of the nose, and cough nearly always characterize the disease during this period; the temperature remains normal or is slightly elevated; in light forms of the disease the duration is from five to seven days.

When the attack is more serious, says M. Demelin, at the end of from three to five days of not very pronounced premonitory symptoms, a chill supervenes followed by an elevation of temperature, which rises to 102.6° and 104° F.; then symptoms of an intense bronchitis, of pneumonia, or of broncho-pneumonia appear. Very often at the end of twenty-three days the alarming symptoms disappear, the temperature falls, and the patient seems to be on the way to recovery. This condition, however, is deceptive, and more frequently the fever and the pulmonary symptoms return for some weeks, and it is only gradually that the temperature falls until it reaches the normal. According to Séguel, the temperature occasionally falls after confinement, but only to rise again. Relapses are frequent. Among the complications may be mentioned pleurisy, purulent conjunctivitis, abscess of the vulvo-vaginal gland, phlegmon of the broad ligament, and phlegmasia alba dolens.

There is, says M. Demelin, a tendency to admit that Pfeiffer's bacillus is not easily pyogenic, and that post-grippal suppuration is ordinarily due to the pneumococcus or to the streptococcus. Grippé evidently favors, during confinement, the development of infections which, without this disease, would probably not develop; it also increases the virulence of the microbes.

In the new-born the respiratory troubles of a grippal nature are very rare, according to Fiessinger, Comby,

Gassicourt, Vinay, and others. On the other hand, Amann, Townsend, Ballantyne, Heunig, and Labadie-Lagrave report cases in which the influenza attacked both mother and child. Strassmann gives a description of this disease in the new-born in which he says that the onset occurs on the third, the sixth, or the ninth day. One symptom which he particularly calls attention to is the lowering of the temperature. Runge, on the contrary, has observed pyrexia. There exists coryza with a formation of crusts around the nostrils, hoarseness, and diarrhoea, and respiration is restricted. Emaciation occurs very rapidly. In serious cases the child sinks into a more or less pronounced stupor. The disease lasts for three or four days when it is benign.

According to Comby, says M. Demelin, ocular and auricular complications, and especially pneumonia and broncho-pneumonia, are the most frequent. According to Ruffié, the child may die at the end of three days with tetanic contracture. However, Séguel concludes that grippé rarely attacks the new-born.

When it does present itself in the new-born, is it a question of intra-uterine infection, or a post-partum contagion? It is probable, says M. Demelin, that the two modes of invasion exist.

**The Therapeutic Value of Subcutaneous Injections of Sodium Phosphate.**—The *Province médicale* for October 17th contains an abstract of an article from the *Journal de médecine de Paris* for September 27th in which the writer remarks that a 0.1-per-cent. solution in sterilized water is preferably employed. After the usual antiseptic precautions are taken, the injections are practised in the retrotrochanteric groove. These injections have been employed in tabes dorsalis, hemiplegia, neurasthenia, and progressive myopathic paralysis. In locomotor ataxia the darting pains and the troubles of motility are considerably diminished. Also in other affections marked amelioration is produced. Sometimes this salt has a direct action on the nervous system; the organism seems to experience a functional overactivity, and it produces symptoms of intolerance.

On the whole, says the writer, it may said: 1. That sodium phosphate exerts an action on the organism which is due to the exciting influence which it produces on the central nervous system. 2. That if the injections are carefully administered hypodermically, the solution does not give rise to any local reaction. 3. That the therapeutic value in locomotor ataxia, in neurasthenia, in hemiplegia, and in progressive myopathic paralysis is worthy of consideration. 4. That the hypodermic injections should be carefully watched in order to prevent the appearance of the symptoms of intolerance which are often produced.

**The New York State Association of Railway Surgeons.**—The sixth annual meeting will be held in New York, on Tuesday, November 17th, under the presidency of Dr. C. S. Parkhill, of Hornellsville. The programme includes the following titles: Modern Methods in the Treatment of Fractures, by Dr. R. H. Cowan, of Radford, Virginia; How can we best secure Immobilization in Compound Fractures at or near Articular Processes? by Dr. Z. J. Lusk, of Warsaw; Immobilization and the Treatment of Fractures at the Elbow Joint, by Dr. J. H. Glass, of Utica; Injuries to the Head, by Dr. Roswell Park, of Buffalo; The Relief and Hospital Department, by Dr. Frank H. Caldwell, of Waycross, Georgia; the president's address, by Dr. C. S. Parkhill,

of Hornellsville; Traumatic Neurasthenia, by Dr. J. E. Walker, of Hornellsville; Cases of Apoplexy following Some Time after Accidents, by Dr. William Browning, of Brooklyn; Cranial Injuries, by Dr. W. A. Ward, of Conneaut, Ohio; Distinctive Features of Railway Surgery, by Dr. R. S. Harnden, of Waverly; Granulation Surfaces, by Dr. John Van Duyn, of Syracuse; Chloroform Anesthesia, by Dr. Webb J. Kelly, of Galion, Ohio; Injuries to the Eyeball, by Dr. Samuel Mitchell, of Hornellsville; Acute Infective Thetitis, by Dr. A. Llewellyn Hall, of Fair Haven; and Compound Fracture of the Skull, with Injury to the Brain Substance, with a Report of Cases, by Dr. J. G. Kelly, of Hornellsville.

**Proposed Changes in the Form of Death Certificate in New York.**—President Wilson and Commissioner Fowler, of the health department, have done us the honor to ask for our opinion of certain proposed changes in the death-certificate blank. They are as follows: On the face of the blank, a question is added as to how the deceased had been fed if he was less than a year old, and the division of the causes of death into "chief cause" and "contributing cause," also a statement of the duration of the disease, are dispensed with. Instead of what is now printed on the reverse side of the blank, the following is proposed:

"N.B.—A certificate of death is a document of great importance. More than ten thousand copies of such certificates are issued annually from this office, for use as legal proof of death here and abroad. It is essential, therefore, that the particulars called for shall be given correctly, legibly, and as fully as possible.

#### TO PHYSICIANS.

"1. The attending physician must furnish a certificate within thirty-six hours after death (Sanitary Code, sec. 151).

"2. All physicians practising in New York city (including those in public institutions) must be registered in the bureau of records (Sanitary Code, sec. 5).

"3. If a person dies from criminal violence, or by a casualty, or suddenly while in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, the case must be referred to the coroner's office (chap. 410, sect. 1773, laws of 1882).

"4. Certificates will be returned for additional information, which give any of the following diseases, without explanation, as the sole cause of death:

"Abortion, childbirth, gangrene, meningitis, necrosis, pyæmia, abscess, convulsions, gastritis, metritis, peritonitis, septicæmia, cellulitis, erysipelas, hemorrhage, miscarriage, phlebitis, or tetanus. (Any one of these may be the result of an injury, and thus be a subject for investigation by a coroner. If it is not, the certificate should make that fact plain.)

"5. No certificate giving 'heart failure,' 'dropsy,' or other mere symptom as the sole cause of death will be accepted, unless accompanied by a satisfactory written explanation.

#### TO UNDERTAKERS.

"1. No burial permit can be obtained without a proper certificate.

"2. Certificates must be written throughout in black ink.

"3. No certificate will be accepted which is mutilated, illegible, or inaccurate, or any portion of which has been erased, interlined, corrected, or altered, as all such changes impair its value as a public record."

We may say that we approve of these changes entirely.

In addition to these changes in the form of the certificate of death, it is proposed to issue a small pamphlet containing, in as brief and condensed a form as possible, the information indicated by its title, viz.: Legal Duties of Physicians, Midwives, Undertakers, and Cemetery Keepers, and the Regulations of the Health Department relating to the same. Every person interested will be supplied with one of these pamphlets, and, if it is preserved for reference, it is confidently expected that most, if not all, of the causes of misunderstanding between physicians and the health department will be removed.

**The Action of Thyreiodinin in Cachexia Strumipriva.**—At a recent meeting of the Imperial-royal Society of Physicians of Vienna (*Wiener medizinische Blätter*, October 22, 1896) Dr. J. A. Notkin presented a paper on this subject. From early observations of his own he had drawn the inference that the phenomena caused by extirpation of the thyroid gland were divisible into two classes, one being the symptoms of tetany and the other those of myxedema. He thinks it probable that the phenomena of myxedema occur only when there is left some remnant of the thyroid parenchyma capable of performing its functions, also that myxedema is caused by an albuminous principle, thyreoproteid, whereas tetany depends on poisoning with products of metabolism which are not of an albuminous nature. Baumann's thyreiodinin will cure goitre and myxedema, but it has been difficult to assume *a priori* that it would also cure tetany. It appears from data furnished by Frinkel, Koher, Jr., and Gottlieb that besides thyreiodinin (or iodothyrein) the thyroid gland contains other specifically active substances.

The author had undertaken an experimental investigation of the truth of Baumann's contention that thyreiodinin would cure all the results of removal of the thyroid gland. In the first experiment, the entire gland was removed from a dog. Two days later there were fibrillar and occasionally clonic contractions of the muscles of the limbs. On that day and on the following day forty-five and sixty grains of thyreiodinin respectively were given to the animal; nevertheless, the most pronounced cachexia strumipriva was developed. The dog was now almost dead, when, by means of a stomach-tube, forty-five grains of Merck's preparation of dried thyroids were introduced into its stomach. In the evening the convulsions ceased, and on the following day forty-five grains more of the Merck preparation were given. On this day and the next the dog was lively and free from convulsions. Now in the course of two days a hundred and eighty grains of thyreiodinin were given to it, and again fibrillar contractions showed themselves, and there was an attack of tonic and clonic convulsions.

In the second experiment, thyreiodinin also proved incapable of causing the subsidence of the tetanic symptoms; indeed, they became more intense under its employment, and even when injected subcutaneously it failed to affect them.

In the third experiment, the animal was treated with thyreiodinin beforehand. In spite of this and of the large doses employed after the onset of the convulsions, the dog could not be saved from the severest symptoms of the cachexia. The urine of all the three dogs was albuminous.

From these experiments Notkin concludes that thyreiodinin is incapable of overcoming the phenomena of tetany; however, he did not use Baumann's own

preparation, and this may account for the difference between his and Baumann's results.

**Menstruation and Ovulation in Monkeys.**—Mr. Walter Heape has been studying the reproductive functions in certain species of monkeys. Some time ago he published an account of his observations of *Scenopithecus endellus* with reference to menstruation, and more recently, in the *Proceedings of the Royal Society*, No. 361, there has appeared an abstract of his essay on menstruation and ovulation in *Macacus rhesus*. It seems that this monkey has a definite breeding season, but that the season occurs at different times of the year in different parts of India. Mr. Heape mentions congestion of the skin of the abdomen, legs, and tail, swelling and congestion of the nipples and vulva, and flushing of the face as prominent external signs of menstruation. A regular menstrual flow occurs, consisting of a viscid, stringy, opaque white fluid filled with granules and containing also red blood-corpuscles, pieces of uterine tissue, both stroma and epithelium, and also leucocytes.

Mr. Heape has met with only one case in which it could possibly be supposed that ovulation and menstruation occurred simultaneously; this was the only case in which a recently discharged follicle was found in the ovary of a menstruating *Macacus rhesus*. It does not follow, he says, that ovulation in this case was brought about by menstruation; indeed, the absence of any sign of the recent bursting of a follicle in any other of the seventeen cases examined is in itself strong presumptive evidence that the two processes are distinct. This result may be confidently asserted for *Macacus rhesus* during the non-breeding season; at the same time, he adds, it must be remembered that he has not investigated *Macacus rhesus* during the pairing season; at that time, he thinks, ovulation may be more frequent, and may often be coincident with menstruation; but, however that may be, menstruation occurs in *Macacus rhesus* regularly without ovulation taking place, and his former views are confirmed—namely, that ovulation does not necessarily occur during each menstrual period, and that it is not necessarily brought about by menstruation.

He feels warranted in going further than this and asserting that the regular occurrence of menstruation without ovulation, even in the non-breeding season, is sufficient evidence that ovulation is a distinct process, and that it depends upon a law or laws other than the laws which govern menstruation.

Throughout, no trace of a blood clot within the follicle was seen, and therein, he remarks, these ruptured follicles differ from what is usually described as a normal ruptured follicle in the human female. This difference between two animals both of which undergo menstruation he thinks remarkable and worthy of special attention. He has some reason to believe the difference may be due to the presence or absence of the breeding season in monkeys, and to periods in the human female which are in the one case favorable and in the other case not favorable to conception. If this is true, he says, the period of the human female which is unfavorable to conception would be comparable to the non-breeding season of monkeys, and the period favorable to conception with the breeding season of monkeys. He does not maintain that among civilized peoples at the present day there are definite breeding and non-breeding times, but he thinks the comparison is in harmony with the view that at one period of its existence the human species had a special breeding season.

### AIDS IN OBSTETRIC TEACHING.\*

By JAMES CLIFTON EDGAR, M. D.

#### INTRODUCTION.

THE underlying principles of obstetrics are based upon certain recognized and well-known laws of anatomy, physiology, and physics, which allow of a wide range of illustration.

Without a question, the best single method for the student to acquire a practical and lasting knowledge

with the main principles of the subject, or his attention is fixed at the time by means of abundant illustration, especially regarding the anatomical and mechanical principles involved, much of his practical experience goes for nothing and is wasted upon him. The shortcomings of the theoretical or didactic obstetric lecture has in the past few years received considerable attention, but most of those who have arraigned the didactic form of instruction in the strongest terms have offered us no substitute other than a general plea for more practical work.

As I stated in the preceding paper, I believe a modified theoretical lecture still has its place in obstetric

FIG. 9.—A represents the model finished in clay and ready to receive the first coat of paper strips moistened in water; B represents the clay model covered with the first layer and the application of the paper strips dipped in hot carpenter's glue; C shows a transverse section of the completed paper model, with its interior filled with excelsior, and the surface ready for the first coat of paint.

of midwifery is in the personal and actual care of parturient and puerperal women—no student, however, should be allowed this privilege without previous training—and in witnessing various obstetrical procedures in a clinic; but unless his mind has been made familiar

teaching—namely, a didactic lecture that is in part recitation, in part demonstration, and which is freely and abundantly illustrated by various means, some of which I suggest in this paper.

Not a decade ago the memory was the only faculty appealed to and cultivated in the teaching of obstetrics. The student's mind was made the recipient of isolated facts, and required to retain them by brute force as it were. That memory has its place and is an important factor we make no question, but it is the power to ob-

serve, to grasp, to comprehend, to utilize, to put two and two together and reach a logical conclusion—that is the fundamental principle of practical education.

It has been for the readier and better cultivation of those two faculties of the mind, so essential to the medi-

cal student, of the instructor in the recitation room may be absolutely wasted upon the pupil, whereas were simple and familiar objects and models, which possess the third dimension of space, made use of in conjunction with the description, the subject would immediately appeal to

FIG. 16.—Gravid uterus at end of sixth month ( $8\frac{1}{2} \times 6\frac{1}{2} \times 6\frac{1}{2}$ ). Ovoid gradually becoming egg-shaped. Posterior wall flattened by spinal column. Tubes considerably below horns. Size and shape influenced by fetus, placenta, liquor amnii, and disease. (Paper model;  $\frac{1}{2}$  natural size; from a photograph.)

FIG. 17.—Gravid uterus at end of seventh month ( $10\frac{1}{2} \times 7\frac{1}{2} \times 8\frac{1}{2}$ ). Egg-shaped. Broadest just below fundus. Longitudinal axis predominates. Posterior wall flattened by spinal column. Tubes still farther below horns. Size and shape influenced by fetus, placenta, liquor amnii, and disease. (Paper model;  $\frac{1}{2}$  natural size; from a photograph.)

reading and his class-room work, encounter many new and unfamiliar words, or many which have heretofore been used in quite another sense, and, moreover, to such an extent that he completely fails to grasp the underlying principles that they are intended to convey. Thus, an elaborate description in the text-book or on the part

object is presented. The model succeeds since the reverse obtains. Take, for example, the flattened pelvis of rachitis. The student's interest is immediately awakened and held if such a pelvis be placed in his hands with the request to point out the departures from the normal condition.

Injuries to the pelvic floor become much more real and easily understood when reproduced in casts, with real sutures in place, than by chalk on the blackboard or diagrams in text-books. So, too, the history of the

So in the description of the involution of the puerperium and the relations of the uterus to the surrounding parts, paper reproductions of frozen sections will render us great service in holding the student's attention and

where the rules of the institution debar the nurse from actually conducting the confinement, or even making a vaginal examination.

Objection is occasionally raised, justly or unjustly, that general obstetric demonstration, apart from the bedside or clinic, carries with it the necessity of handling wet and dried anatomical material—fœtal cadavers, for instance—and, consequently, a suspicion of uncleanness.

Not the least advantage of the greater number of the

specimens of pelvic deformity, and an interchange of such models, together with their clinical history, may accomplish much to raise the standard of obstetric instruction.

#### PROPER PLACE FOR MODELS—CAUTIONS REGARDING THEIR USE.

I desire at the outset emphatically to disclaim any intention of implying or suggesting that the aids in obstetric teaching herein described and illustrated are

FIG. 25.  
Mechanism of cervical dilatation in primiparae (diagrammatic). (Paper models: from a photograph.)

FIG. 26.

aids in obstetric teaching herein described is to be found in the fact that by reason of their composition they may be made and kept obstetrically clean—no small advantage, since we often desire to use the same at the bedside or in the obstetric clinic.

in any sense to replace practical bedside instruction. These aids I offer as auxiliaries, as adjuncts for more instructive and interesting obstetric recitations, demonstrations, theoretical lectures, clinics, examinations of pregnancy, and ward instruction in maternity hospitals.

FIG. 27.  
Mechanism of cervical dilatation in multiparae (diagrammatic). (Paper models: from a photograph.)

FIG. 28.

Much that I present in these pages is suggestive and rudimentary in character; much, we feel, can and will be improved upon as time and opportunity offer. For example, I beg leave to suggest that plaster molds be taken of specimens of pregnant uteri of known months of gestation, so that from these subsequently any desired number of *papier-mâché* models may be reproduced for exchange among museums and obstetric teachers. The same plan may, I believe, be pursued in the case of

I can confidently assert, as the result of several years' experience in the use of such aids, that they throw new light upon many physiological and mechanical problems of midwifery, and that they moreover lend new interest to many obstetric subjects, which, by reason of their obscurity and dryness, have in the past proved more than stumbling blocks to students, and, I may truthfully add, to practitioners as well.

It can not be too strongly insisted upon that great

FIG. 29.—Vertical mesial section of the pregnant uterus at the beginning of the fifth month of gestation. (Paper model; from a photograph.)

FIG. 30.—Vertical mesial section of puerperal uterus five minutes after delivery. Patient died, heart disease. (After Webster; paper model; from a photograph.)

FIG. 31.—Vertical mesial section of puerperal uterus second day of puerperium. Patient died of eclampsia thirty-six hours after labor. (After Webster; paper model; from a photograph.)

FIG. 32.—Vertical mesial section of puerperal uterus three days after labor. Patient died of acute yellow atrophy. Nearly full term. (After Webster; paper model; from a photograph.)

care must be employed in the selection and use of models as aids in obstetric teaching. Their proper place must be constantly kept before us, and where reproductions from Nature in paper, plaster, composition, or rubber are employed, we have found it safer and generally more satisfactory to produce the natural size of the object, as by enlarging, the subject may become merely grotesque, or even convey a false impression. A wrong impression, moreover, readily acquired, is often less easily corrected in this connection.

If proper care is taken in the selection and preparation of models, no false or exaggerated impression will be conveyed, and the production of models in three dimensions of space, at which we always aim, secures for us a means of ocular demonstration and illustration, which diagrams and charts, be they ever so beautifully executed, or even blackboard illustration with an abundant supply of colored chalk, can never equal. Diagrams are unsatisfactory; they soon become tiresome to the student, and they may be misleading because of the loss of the third dimension of space.

The attempt on the part of the student to acquire a correct and clear idea of certain fundamental obstetric principles from a study of a

FIG. 36.

FIG. 37.

FIG. 35.—Complete rupture of the uterus involving left lateral and posterior walls and extending from the contraction ring almost to the external os, which latter is intact. Also complete rupture of posterior vaginal wall just below external ring, opening into Douglas's pouch. (After a specimen in the Museum of the Munich Frauenklinik; paper model; from a photograph.)

FIG. 36.—Complete rupture of the left posterior wall of the uterus, extending from the contraction ring downward and inward across the lower uterine segment, through the external os, and some distance down the posterior

vaginal wall. This illustrates a particularly dangerous form of rupture of the genital tract, because of the possibility of direct infection of the peritoneal cavity by the vaginal secretions. (Paper model; from a photograph.)

FIG. 37.—Transverse rupture of the uterus through the lower uterine segment at a point halfway between the contraction ring and the external os. Cancer of the cervix. Vertical mesial section. (Paper model; from a photograph.)

series of illustrations in his text-book or in the lecture room is very apt to result in a condition of bewilderment on his part, which could readily have been avoided by the free use of a few simple models. With such models, recitations and demonstrations to classes divided into easily handled sections can be made to

FIG. 34. Vertical mesial-section of pariparous uterus half horn after labor. Contracted pelvis. (After Stratz; papier-mâché; from a photograph.)

result in much practical gain to the student, who has up to this point obtained his knowledge of obstetrics from text-books merely.

#### VARIOUS KINDS OF AIDS.

For purposes of convenience we shall enumerate and describe the several kinds of aids to obstetric teaching included in this paper under the following headings:

##### I. Plaster models.

##### II. Paper reproductions of clay models and plaster casts.

##### III. Composition models.

##### IV. Miscellaneous models and aids.

##### V. Electro-plated casts and models.

#### I. Plaster Models.

Experience has taught us that plaster models *per se* have a very limited field in this direction. Unless the subjects be small and compact, the tendency of the plaster to break, and the excessive weight in the case of the large ones, are decided objections.

Plaster, however, will answer very well for the smaller uteri of the early months, and has been of service to us in securing first impressions of lacerations, pregnant uteri, external genitals, etc., which are subsequently reproduced in paper, composition, rubber, or rendered serviceable and durable by electro-plating with copper, as described hereafter.

#### II. Paper Reproductions of Clay and Plaster Models.

After experimenting with various kinds of papier-mâché, papier-mâché compositions, and modified plaster, we have found the method proposed by Dr. W. G. Thompson\* as best suited for our purpose, because of the lightness, durability, and cheapness of the models made by this process.

In addition to the plaster model, all that we require is an abundant supply of old newspapers, some carpenter's glue, shellac, or a good varnish, and some ready-mixed paints. The clay model or plaster-cast model having been made (see Fig. 9, A), it is first covered on one side with a single layer of small pieces of newspaper (two by four) moistened in cold water (see Fig. 9, B). Every portion of the model or cast is thus covered with a single layer, and rapidly laid upon this layer successive layers of paper dipped in hot glue are added. By means of a flat brush time is saved by painting the glue over the surface and rapidly laying the strips of paper upon it. Special care is needed with the last layer of strips only, in order to secure a smooth surface (see Fig. 9, C). The number of layers and subsequent thickness of the wall should depend upon the character and size of the model. In large models wire gauze, strips of cheese cloth, cardboard, and even thin slabs of pine, may with advantage be incorporated with the paper and glue to add stability. The casing is now allowed to dry thoroughly upon the clay or plaster mold, and is then removed either entire or in two or more sections when the former can not be done (see Fig. 9, C).

If the model represents, for instance, a sagittal section, the interior is now carefully stuffed with loose newspaper or excelsior, and a back added by means of larger

\* The Use of Automatic and other Models in teaching Physiology. *Researches of the Loomis Laboratory*, vol. ii, 1892.

pieces of newspaper, strengthened with cheesecloth, glued in the same manner as the above (see Fig. 9, C). When this has thoroughly dried, a couple of thick coats of paint are applied, to represent the object, and the whole shellacked or varnished. For accuracy in the reproduction of frozen sections (see Figs. 20, 29, 30, 31, 32, 33, and 34), diagrams of sagittal sections (see Figs. 22, 23, 24, 25, 26, 27, and 28), pathological specimens (see Figs. 35, 36, and 37), we have photographed the cuts or rephotographed the photographs, then with an enlarging lantern thrown the outline of the figure upon a sheet of the thinnest tissue paper until the desired size was obtained, and outlined the object with a heavy pencil. Then, placing the paper upon the smooth layer of clay, the modeling is done directly through the paper, the moisture of the clay finally absorbing the tissue paper. Thus, absolute accuracy of detail and relationship can be obtained. The reproductions of Webster's frozen sections (Fig. 20) were made in this manner.

"When finished, the model becomes as hard as board and it possesses great advantage over *papier-maché*, which is more expensive and usually brittle, unless subjected to great pressure.

"This new composition is smooth and very hard, watertight (for cold water), it never warps, breaks, or cracks, and when painted it is difficult to believe that it has been made of such cheap material."

An almost endless variety of anatomical and physiological obstetrical models may be thus secured.

Transverse and sagittal sections are reproduced, as shown above. Where oval or round objects, as pregnant uteri or tumors, are to be reproduced, the entire specimen is covered with the paper as above described, allowed to dry, then cut in halves, the clay or plaster allowed to drop out, and the two shells stuffed with excelsior and glued together with several layers of paper strips overlapping at the seam.

1. Size and shape of the uterus during the successive months of gestation.

These paper models here illustrated are, with the exception of the normal uterus, not taken from Nature, but are founded upon the collective descriptions and average measurements given by Webster, Hart and Barbour, Ribemont-Dessaigners, Farr and Tanner.

Should opportunity offer, more valuable and precise models should undoubtedly be produced by making, immediately after death, plaster casts of gravid uteri, and then subsequently paper reproductions of the same. We would offer here as a suggestion, as we do in another place, that casts of such uteri from the cadaver be made which can subsequently be reproduced in paper and exchanged among obstetric teachers and museums. Many are the uses to which such paper uteri may be put: The height of the fundus in the several months in and out of the pelvis; the changes in the shape of the fundus and lower uterine segment, and their influence upon the attitude, presentation, and posi-

tion of the foetus; placental insertion; physiology and pathology of pregnancy and labor; and many other conditions that will constantly suggest themselves, so that such models will be in almost constant use during a course of obstetric teaching.

2. Vertical mesial sections of uteri at term; mechanism of cervical dilatation.

Fig. 20 is a reproduction in paper of Braune's frozen section of the parturient uterus at the end of the first stage, and Fig. 21 is the same, with a foetal cadaver introduced to illustrate presentation and position.

Fig. 22 is a diagrammatic representation of a vertical mesial section of a uterus at the beginning of the first stage of labor, before the disappearance of the supravaginal portion of the cervix. The uses to which these two models can be put are almost endless, and students in a short time can be brought to appreciate obstetric conditions and situations which hours of explanation formerly were required to elucidate.

For example, the model of Fig. 20 can easily be made to demonstrate the curve of the parturient canal, normal and abnormal attitude, presentation and position of the foetus, displacement of the small parts, and so on.

So the diagrammatic model of the uterus (Fig. 22), with its cervical canal dilated to the size of one finger, has proved of value in exhibiting various forms of cervical dilators, as Tarnier's Barnes's, Champetier de Ribes's, and others, and the advantages and the disadvantages of each; the varieties of placenta prævia; the uses and action of the vaginal tampon; and many other conditions that will suggest themselves to the instructor.

Fig. 24 also represents a diagrammatic vertical mesial section of the uterus, its open side fitted with netting in order to retain the foetal cadaver or puppet during demonstrations of the intra-uterine manipulations accompanying different varieties of version, reposition of prolapsed small parts, correction of malpositions and postures.

The models representing cervical dilatation in primiparæ and multiparæ, in Figs. 25 to 28, will, to a more limited extent, be found useful.

3. Reproductions of frozen sections of gravid and puerperal uteri.

It has been with some hesitation that I have attempted the reproduction of the frozen sections of Webster and Stratz for fear that something of the original would be lost or distorted in the paper model. We have therefore confined our work to the grosser ones, as the puerperal uteri of Webster. In only one instance have I attempted to produce a model of the gravid uterus and its contained ovum (Fig. 29), and the result was not altogether satisfactory. For such illustrations quite as much can, we believe, be accomplished by diagram.

The series of models representing involution, position and relationships of the puerperal uteri, after Webster's frozen sections, we have found of marked aid in

demonstrating many conditions associated not only with the physiology, but also the pathology of the perium\* (Figs. 30 to 34).

#### 4. Rupture of the uterus and vagina during labor.

These models were made with a view to illustrating the most frequent site of uterine rupture, the relation of the rupture to the contraction ring and external os, and the greater danger of infection when the tear involves the vagina as well as the uterus.

(To be continued.)

## A CASE OF CONGENITAL HYPERTROPHY AND STENOSIS OF THE PYLORUS.

By F. SCHWYZER, M.D.,

PATHOLOGIST TO THE GERMAN HOSPITAL, NEW YORK.

IN April, 1894, I had the opportunity to perform an autopsy on a girl, three months old, who had died with the symptoms of chronic gastritis. The small body was atrophic to a high degree; abdomen not distended. Lungs, heart, spleen, kidneys, and genital organs showed nothing worthy of mention. The intestines were, for the most part, empty and anæmic. The large intestine displayed, both in the transverse colon and in the sigmoid flexure, a constricted portion about one and a half to two centimetres in length. The wall in the intestine at these places was thin, the diameter of its lumen only two thirds that of the other parts of the large intestine. Except for the atrophic appearance of the mucous membrane and the muscularis, nothing of interest could be demonstrated at these stenosed parts of the gut, not even microscopically.

The stomach measured, from the fundus to the pylorus along the greater curvature, twelve centimetres; from the small curvature to the larger, at its largest diameter, five and a half to six centimetres. The cardiac end exhibited no changes. In place of the pylorus, however, a round tumor presented itself, 2.4 centimetres in length and 2.1 centimetres in thickness. The stomach contained a scanty amount of mucous fluid and some curdled milk. The thickness of the stomach wall averaged three to four millimetres. Its mucous membrane was slightly corrugated, its folds radiating toward the pylorus. As regards the tumor in the pyloric region, this felt rather hard and constricted the lumen of the pylorus to such an extent as to allow a probe, two millimetres in diameter, barely to pass. The mucous membrane was quite thick, two to two and a half millimetres, and folded longitudinally; at no place was it ulcerated or otherwise changed. Submucosa and muscularis presented such a coarsely fibrous, unyielding wall of five to six millimetres' thickness that the diagnosis of scirrhus pylori suggested itself. But, inasmuch as the mucous membrane was not ulcerated and no cellular elements could be scraped off from the cut surface of the pyloric wall,

and inasmuch as neither the liver nor any other organ exhibited metastatic deposits, the final diagnosis was reserved for the microscope.

The liver showed centrally in the acini atrophic changes, fatty infiltration peripherally. Pancreas and suprarenal capsules were unchanged.

Accordingly, the anatomical diagnosis was: Stenosis of the pylorus, atrophic changes in certain parts of the intestine, and a very pronounced general atrophy.

The microscopical examination of the pylorus shows a somewhat thickened, otherwise normal mucous membrane. Submucosa and muscularis mucosæ together formed a coarsely fibrous texture with many smooth muscle fibres. This tissue, on account of its sclerotic character, stained with some difficulty. Epithelioid cells could not be found in this tissue, nor did the epithelium of the mucous membrane in any place extend into the deeper layers of the mucosa. Transverse and longitudinal sections of the pyloric tumor were made and stained with the usual method. On examination of these sections it was found that the outer layer of the muscularis was composed of longitudinal, smooth muscle, whereas the remainder of the muscularis was made up of circular muscle fibres. The former was one to one millimetre and a half in thickness, the latter three and a half to four millimetres. The outer layer was of a continuous, uniform make-up, and consisted of smooth muscle fibres. The inner layer, on the contrary, exhibited muscle fibres aggregated in large, ringlike bundles, interspersed by smooth strips of sparse connective tissue containing blood-vessels. The peritoneal covering was slightly thickened, otherwise normal. There was, consequently, no other possible diagnosis except that of simple hypertrophy of the pylorus, and under this diagnosis I presented this anatomical preparation at one of the scientific meetings of German physicians taking place at Dr. A. Jacobi's.\*

Sections were also made of both atrophied and stenosed places in the colon. No microscopical abnormalities were discovered, with the only exception that all the three layers of the intestinal wall were thinner than the remainder of the colon. No inflammatory changes of any kind could be detected.

The symptoms which the child had shown during life were, in short, as follows: The child was well developed at birth, weighed eight pounds and a half, and during the first two weeks she thrived very well on mother's milk. Then she began to vomit occasionally. She cried frequently after feeding, and suffered from repeated attacks of slight diarrhoea. The stools were, at times, somewhat greenish in color, but never showed any evidence of serious intestinal catarrh. The condition of the patient during the sixth and seventh weeks was improved by washing out the stomach, and the improvement was such as to enable it to again partake of food for a day, and this apparently without any disturbance. But soon the vomiting recurred, so that finally the stomach tolerated no food at all, even when given in teaspoonful quantities. Washing out the stomach brought up some mucus: the reaction of the gastric juice was acid, in part due to a trace of free HCl. In the ninth week feeding by mouth was discontinued, since, by the occurrence of violent convulsions, the parents of the child had been prejudiced against the stomach washings. For two weeks longer the little pa-

\* Barbour, in the *Edinburgh Medical Journal*, October 18, 1895, in a series of papers upon the study of frozen sections, after passing in review the various sections described by different investigators, makes an estimate of the value of this method of study, as follows: Barbour considers that, by means of such sections, we have gained most in knowledge regarding the birth canal. He acknowledges the limitations which are inevitable in such study, but considers that we have by this method acquired ideas which have revolutionized our conceptions of study

\* The report is printed in the *Deutsche med. Monatsschrift*, 1895, No. 6.

tient was kept alive by giving nutritive enemata. Then, in the eleventh week, the child died.

The anatomical diagnosis of this case is cleared up by the microscope. We find an immense hypertrophy of the wall of the pylorus. The stenosis may have been primary or may have arisen secondarily with the progressing hypertrophy and unyielding contraction of the pyloric ring. The circumference of the mucous membrane of the pylorus is so small that we assume not only a hypertrophy, but also a congenital stenosis of the pylorus.

The so-called stenosis and hypertrophy of the pylorus was first described by Landerer (1). Later on, in the year 1885, R. Maier (2) published thirty cases, nearly all of which concerned adults, a few only of children over ten years of age. None of these bears comparison with our case. Tilger (3) published in the year 1893 a very thorough and elaborate treatise on *Hypertrophy of the Pylorus*, adducing, at the same time, quite a literature on this subject. Nearly always did it relate to adults. Hirschsprung (4) was the first one to describe, in the year 1888, stenosis of the pylorus referable to infancy. He gives an account of two cases. The first case was a girl, which ten days after birth began to vomit and which on the thirtieth day died, utterly emaciated. The pylorus consisted of a cylindrical thickening two centimetres and a half long; its lumen permitted the passage of a medium-sized probe. All parts were concerned in the hypertrophy, chiefly, however, the muscularis coat. The second case exhibited stenosis symptoms from the third month of its life, and died in the sixth month. The pylorus had a total length of three centimetres and allowed the passage of a lead pencil. Peden (5) refers to a similar case. A child, vomiting almost from the time of birth, dies after three months, showing a considerably thickened pylorus, the lumen of which was five millimetres in diameter. Submucosa displayed hypertrophy to a high degree, the muscularis to a less. Pitt (6) observed a like case in an infant of six weeks.

Thus the four cases last described are fairly similar to our case.

As regards the ætiology of this affection, it seems to me quite doubtful that all the so-called cases of congenital hypertrophy of the pylorus are in reality cases which developed during intra-uterine life. We must by all means draw a dividing line between cases which during infancy yield no or hardly any symptoms, and such as give symptoms and still do not shorten life until about the time of full development, and, thirdly, such cases as lead to death during infancy. These latter cases are certainly congenital, inasmuch as they give rise to serious disturbances in the first weeks of life. It seems to us highly improbable that cases like those of Pilliet (7) and Clodivilla (8) can be called congenital, as both these cases referred to old age. Maier adduces that the closure of the foramen Winslowii might be an ætiological factor.

According to the above-mentioned literature, congenital stenosis and hypertrophy of the pylorus does not appear to be at all such a rare affection; all the more important is it, therefore, to make the diagnosis *in vivo*. We must think of congenital stenosis and hypertrophy of the pylorus as soon as a child suffers from constant vomiting without apparent cause, and especially without symptoms of a gastritis or enteritis, and, above all, if three or more hours after taking food nearly the whole quantity can be removed by a stomach tube.

In our case the diagnosis might have been arrived at, inasmuch as the child could retain absolutely nothing on its stomach, and was subject to continual vomiting attacks. Closure of the gut, however, could be excluded in this case, as the child vomited at no time either faecal matter or bile.

Thus the diagnosis would depend upon:

1. Constant vomiting, without any clinical reasonable cause (such as meningitis, etc.).
2. Evidences of retained stomach contents due to motor disturbances in the propelling forces.
3. Absence of occlusion symptoms in the intestines.
4. The ease with which, in the presence of the collapsed intestines, the stomach, and especially the rather hard pylorus, permits of palpation.

The diagnosis being once established, surgical interference alone will be of any avail or benefit to the patient—either Loreta's operation (laparotomy, opening the stomach, and dilating the stenosed pylorus) or else simple gastro-enterostomy.

*Annotation.*—Microscopical investigations regarding the ætiology of the congenital hypertrophy and stenosis of the pylorus have contributed in delaying the appearance of this paper. Since the issue, however, of two articles on the congenital stenosis and hypertrophy of the pylorus during infancy, by H. Finkelstein (9) and Chr. Gran (10), I now no longer hesitate in publishing this case, which might contribute to the knowledge of this rather unknown though hardly rare disease.

Finkelstein reports a case in which, *intra vitam*, the diagnosis of pylorus tumor, causing gastrectasy, had been made. It treated of a girl three months old that, in spite of the most energetic treatment, vomited constantly. After she had been under the author's care for four days she died. The autopsy revealed a macroscopical appearance similar to ours. The stomach was dilated; the pylorus displayed itself as a cylindrical thickening 2.2 centimetres in length and 1.5 centimetre in thickness. The mucous membrane, at the entrance of the pylorus and in the pylorus proper, was in a tumid state and reddish in appearance. The thickness of the pyloric wall was five millimetres, the major part of which belonged to the muscularis. There is considerable difference, however, in the microscopical appearance of Finkelstein's case and ours.

1. He found marked infiltration of the mucous

membrane and the submucosa, with small polyplike prominences (whereas in our case the mucosa exhibited hardly any changes).

2. The thickening of the pyloric wall consisted of longitudinal fibres.

Of the three cases of Gran's which came to the autopsy table, two of them showed slight ringlike stenosis of the pylorus, whereas the third one exhibited marked stenosis. The case was a girl four months of age, who for two months had been subject to frequent attacks of vomiting, and who, finally, on account of this incessant vomiting, was admitted into the Charité at Berlin. There she died two weeks after admission.

The repeated chemical examinations of the stomach contents showed either no or only a slight trace of free hydrochloric acid; now and then a trace of lactic acid; no peptones, but sugar. The digestion of milk seemed to be more impaired than that of barley water. Microscopically, there was found in the stomach contents yeast, cocci, short, rodlike bacilli, but at no time any sarcinae. One bacteriological examination demonstrated the presence of the *Bacterium coli commune*. The clinical diagnosis arrived at was motor insufficiency and atony of the stomach. At the autopsy the stomach was found not very much dilated, the pylorus thickened. It showed hypertrophy of all its layers, especially, however, of its circular muscle fibres. The lumen of the pylorus measured three millimetres in diameter.

Of the four new cases that of Finkelstein forms an exception, as it showed the thickening of the pylorus to be due to a hypertrophy of the longitudinal muscle fibres. The circular fibres, which in all other cases cause the thickening of the pylorus, were in this case but slightly developed.

On the other hand, a case of Gran's, that of Frieda W., presented microscopical appearances similar to ours.

Diagnostically, Finkelstein arrives at the same conclusions as we do; calls, however, attention to differentiate from carcinoma pylori (unique in infants); furthermore, to obstructing polypi, tumors of the neighboring organs, etc.

That the diagnosis is possible during life is proved by Finkelstein's case as well as by some patients of O. Heubner. The latter showed moderate stenosis. By dietetic measures these patients were kept alive, some of them improving even a great deal. It is a pity, however, that Finkelstein, in spite of his clever diagnosis, did not resort to surgical interference, probably because the case came too late under his observation.

## PECULIAR SYMPTOMATA OF SYMPATHETIC DISTURBANCES.\*

By GEORGE E. BILL, M. D.,

HARRISBURG, PA.,  
MEMBER OF THE DAUPHIN COUNTY MEDICAL SOCIETY AND OF  
THE PENNSYLVANIA STATE MEDICAL SOCIETY;  
FELLOW OF THE HARRISBURG ACADEMY OF MEDICINE.

I THINK that the fellows will agree with the reader that one of the bugbears in the study of medicine is embraced in the phrase—the sympathetic nervous system.

In most of the curricula of medical schools very brief mention is made of the sympathetic nervous system, outside of a cursory survey of its anatomical relationship, for the main reason, I apprehend, that, owing to the minute, almost microscopic, tracery of its network, its ramifications, being remote from its central and anastomosing ganglia, are with a difficulty relatively absolute with the present imperfection of the microscope to be followed up into its visceral enfoldment.

So far as I know, there have been no systematic investigations of its clinical rationale until very lately, and these studies have been embraced in monographs emanating very largely from the gynecological and rectal fields of medical research, therein receiving, I believe, original impulse from observations regarding sympathetic pressure disturbance or so-called nerve-pinching of some sympathetic area involved in either plastic exudation or swollen parenchyma.

It has seemed and does seem to me that such original observations already alluded to will in time remove that excuse for ignorance, that vague expression of wisdom—namely, the term reflex phenomena, as explanatory of disturbances in the nervation of the sympathetic; when causes thereof can be more or less easily found resident in sympathetic locale, and producing thereby symptomata confined to the affected area or areas, or producing at the same time symptoms in regions of the body more or less remote from the originally more affected sympathetic area.

\* Read before the Harrisburg, Pa., Academy of Medicine, September 25, 1896.

As to the term reflex, who of us can really, clearly, and succinctly explain its meaning as commonly used?

Explanatory in a clinic, it does not have that directness of expression needed in elucidating the causative meaning of a functional or organic disturbance that a medical term should embrace.

We have been obliged to be satisfied with such a usage, but I do not believe that any medical student or any physician ever existed who has not wished that he knew what the rationale of a so-called reflex phenomenon meant, though he might make never so brave a showing to himself or others that he did understand it.

Now, in view of this difficulty, it seems to me that much confusion could be avoided and more knowledge could be gained if we would confine the term reflex to the field of nomenclature wherein it belongs, and more often substitute therefor sympathetic innervation or nervation, as the case may be.

In estimating the symptomatic and biological values of the sympathetic nerve in medical assumptions, why should we so often lose sight of that wonderful fact, so profoundly true and of such tremendous significance, that independent physical life in its broadest sense begins with the protuberant abdomen of the infant so rhythmically rising and falling, in consonance with the fiat of the Almighty, and "He breathed the breath of life into his nostrils," and he lived, even as the breath of life, earth's atmosphere with its fifteen pounds' pressure to the square inch, exerts itself on belly and lung, which to me are the golden bowl of life, containing the silver cord, the sympathetic?

Why should we not remember, again, that, with the onset of physical death and the outward completion thereof, the abdomen flattens and recedes from the anterior plane; when both lung and belly are stilled in death, the golden bowl is broken, the silver cord is loosed, and all of physical life, its nervations and perturbations, are ended in the beginning of the spiritual?

In almost every problem of sickness, of light or grave import, the above fact, so unconsciously and so universally noted by us all, has ever been of the most paramount importance to me since I began to medically think, and the result to me of a so fascinating study has inclined me to believe that the sympathetic nervous system has to do with the majority of functional or organic diseases.

While the same observation may have been noted by each and all of us, have we not been too inclined to accept a too vague explanation of it all in the use of the term reflex?

Are we not too prone to observe and treat ailments too symptomatically, rather than to seek an etiological rationale thereof?

In puzzling over facts observed and recorded by so many authors regarding the phenomena of sympathetic nervation, it has seemed to me that much confusion might be avoided if we used the term direct instead of

the terms indirect or reflex as explanative of sympathetic nerve action; for in the very observations regarding the pressure of or pinching of a certain area or of areas of the sympathetic nerve we get a direct onslaught of the same, while all of the symptomata arising therefrom are effaced by the entire removal of this pressure.

It used to be said, and such an explanation is in some quarters still used, that these phenomena of suffering were reflex in origin rather than direct, but I think that the time has gone by when such an explanation is or can be satisfactory to the majority of physicians.

Now I suppose that case upon case could be piled up in building proof of this statement, and I believe that many cases could be recalled by more than one of us as a support of the same, and yet, at the risk of wearying your patience, I would like to call to your observant attention a few occurring in my own clinic, because they illustrate the central idea of my subject which I wish to emphasize, and concerning which I wish to provoke your discussion—namely, that it is not in the use of the term reflex that we can seek or find a causative explanation of the symptomata of sympathetic irritation, but that the adjective direct should qualify the etiological factor.

A woman, multipara, forty-eight years of age, came to me regarding a diarrhoea of eight years' standing. The attending symptoms were pain before and after defecation of a throbbing character, backache, headache, nausea, anorexia, hot and cold flashes, pain in the back of the head, stiffness in the muscles of the back of the head and neck, aggravated dyspepsia, abdominal bloating, palpitation, and vaginal and anal pruritus. The diarrhoea and many of the symptoms had been often and temporarily controlled by such medicines as physicians ordinarily use therefor, to return with all cessation of drug therapeutics. These symptoms in their entirety pointed to direct disturbance of the sympathetic.

Physical examination revealed only rectal ulcers and fissures. The patient, owing to financial stress, would not receive local office treatment, and resort was had to a one-per-cent. solution of trichloride of iodine, a quart of which I gave her with instructions to receive a rectal injection of half a pint morning and evening. The treatment was adopted, with the result of her having a most unbearably intense itching of the entire inner abdominal tract from the navel down, involving both iliac regions, which persisted for two days, and was followed by an intense headache and rapid pulse, which large doses of morphine did not directly relieve, when Nature herself stepped in with a profuse nasal hemorrhage which swept away her suffering. There has been entire relief from diarrhoea and all of the symptoms for the last two years.

A young gentleman, aged twenty-four years, thin skinned, a blond, with a history of onanism up to sixteen years of age, and a history of chorea at puberty, came to me for relief from the following symptoms: Four or five nocturnal emissions weekly, and physical exhaustion therefrom; memory defective, voice husky and not to be depended upon in singing; trembling in the limbs, enormous appetite, and a sound sleeper; not of a vivid erotic imagination; backache, constipation,

diameter of faeces small; some dyspepsia, weak eyes, ringing in the ears, giddiness, general weakness, and lack of mental or physical concentration; but the most persistent and most annoying symptoms, on which he laid the greatest stress, were a stiffness in the back of the neck and head, a creeping sensation therein, and an intense burning in the eyes, described as involving the eyeballs, whenever he urinated, this burning being more intense whenever he passed small amounts of highly colored urine. The patient invariably observed a seminal explosion following eye-burning and finally connected the two together. Palpitation was only occasionally present. The face was very pale and the physiognomy of the disease was very apparent in the vesico-rectal plane. While this latter point was a guiding factor in the superficial examination of his trouble, a physical research was imperative in establishing its aetiology. Such an examination revealed negative results until the penis and rectum were searched. The anal sphincters were abnormally tight. Here was revealed a local constriction or pressure of the terminals of the sympathetic. The testicles were firm and of normal size, the epididymis being not enlarged or unduly tortuous. The urethra is one of the most irritable urethrae I ever examined. The endoscope revealed patches of granulations and striæ of inflammation here and there throughout the urethral tract, and local treatment was at first difficult to pursue, because of its tendency to cause *emissionem seminis ab examinatione*, several examples of which did happen, and directly after which there was considerable eye-burning. A few rectal dilatations have insured regular and pressing stools of large calibre and a cessation of abdominal bloating. Proper and systematic urethral treatment is ending the emissions, which on several occasions have been diurnal, by relieving the urethral irritability and tenderness. Peculiar symptomata of sympathetic disturbances and irritability have several times been here noted, in that the direct urethral treatment has caused fainting and collapse, relieved by spontaneous nausea, vomiting, micturition, and defecation by this patient in my office. No drugs have been used, for they add fuel to the fire. No warning has been uttered to keep from lewd thoughts and immoral and exciting reading, nor has any regimen of diet been employed, save in one instance an interdiction from soda water, for carbonic-acid gas is an erotic drink in such cases, and in this case always increased his trouble. Ejaculation was always at first premature and without pleasure, and desire was tormenting. The twenty-four hours' collection of urine and the specific gravity thereof were in normal proportion to his body weight; consequently the symptoms apparently remote from the injured sympathetic area, such as burning of the eyes and annoyance in the neck and head, which might be called psychic in their expression, could not be ascribed to lithæmia. It seems to me that all of these symptomata are directly attributable to sympathetic nerve irritation and should not be called reflex, for they are all disappearing with the improvement of the urethral irritability.

A man came to my office suffering from one of the most aggravated attacks of right sciatic irritation I have ever noted, of six or eight weeks' duration. To me the cause of the inflammation was apparent at a glance at his face, for it was visible in the labial physiognomical plane of disease suffering. The right limb was almost helpless, and dragged on locomotion, and he walked with the assistance of a cane. Previous hypodermic medica-

tion had been used without avail. Was there any rheumatic aetiological factor present? Was there any lithæmia present? No, for an examination of the twenty-four hours' urine, with the specific gravity of the same and the body weight, showed only a lack of seventy grains total urinary solids, not enough to obtain a cause in this supposition. Physical examination revealed absolutely negative results outside of rectal. What was found herein? An enlarged, sensitive, tender, and swollen vermiform appendix, verified subsequently by another physician. Pressure on the appendix caused a marked and sudden exacerbation of pain in the affected limb. The pain could not have been caused by my moving the limb on examination of the appendix, because I wished to eliminate this factor if possible, and therefore the examination was very gentle. Again, there was not much pain in the leg in the recumbent position, but there was increasing pain with the assumption of the upright position, owing to the weight of the superincumbent intestines on the appendix. There was much constipation; there were very tight anal sphincters. There was a temperature only half a degree above normal. There was tenderness in the right iliac region on deep pressure, leaving a dull aching thereafter. The iliac percussion note was dull. On inquiry, I found that the patient had slipped and strained the right iliac region two or three days before the sciatic complication made its abrupt onset.

A curious point in this case is that as soon as the sciatic pain was controlled the iliac suffering became more pronounced. The anal sphincters were cautiously dilated; the bowel was oiled out night and morning; the tendency to appendicular inflammation was combated with appropriate remedies; the sciatic involvement was treated with kola celery compound, faradism, galvanism, and hypnotism, and the man is very nearly well after two weeks of treatment and resumed his work on the 14th of this month.

In view of the complication which was the more prominent in the gamut of suffering, it is interesting to note the primary aetiological factor, resident in a nerve-pinching of a sympathetic area, and a fact I have several times noticed, that outward expressions of symptomatic suffering are often revealed in body planes parallel to the seat of the cause.

A young gentleman, thirty-four years of age, came to consult me for almost nightly emissions. He was desirous of marrying, and questioned therefor his physical integrity. His physiognomy revealed a rectal cause, but he said he had not had hæmorrhoids since he was twelve years old, which his physician had attributed to horseback riding. There was no erotic desire or fancy. The urine was normal macroscopically and chemically, and the microscope revealed occasional spermatozoa. There was no spermatorrhœa. He had been treated for a most aggravated dyspepsia, with no permanent results. He had been advised to exercise, a treatment always aggravating seminal emissions. He had taken *nux vomica*, strychnine, phosphorus, damiana, bromides, *ad nauseam*, without avail. He had been advised to read good and prayerful works, which availed him naught. In short, all of the treatment supposed to be and adopted as curative of such troubles accomplished nothing but

to bring the man to the verge of melancholy and suicide. His memory was defective, his bodily powers were waning. The usually so termed psychic symptomata, such as spinal pain and stiffness from coccyx to cerebellum, were markedly present. Examination revealed a large penis, firm and sound testicles, relaxed scrotum. Was there any ordinarily irritable urethra? There was no inflammatory condition of the mucosa, but was its calibre normal to the sound touch? No. It was abnormally tight throughout its whole extent, not admitting the smallest sound. It was practically dead, and for this reason, while examining, I began to despair, for it was one of Ultzman's dicta that, given a dead urethra irresponsive to the stimulus of a sound, you have something very nearly approaching to impotency. But, on examining digitally the rectum, I found what so often exists in parallelism with a tight urethra, an abnormally tightened condition of both anal sphincters, and touching an ulcer behind the inner sphincter caused a very strong erection. On applying a hot sound to the penis, the sensation of heat was not experienced by the patient. The key to the solution of this man's trouble lay, therefore, in the rectum entirely. Dilating the same at weekly intervals at first, applying the static faradaic and galvanic currents to all affected symptomatic areas, and treating the rectal lesions allayed the trouble therein and enlarged the urethral calibre, all of the rest of the symptomata disappeared, and the man is now well and very grateful.

In the service of an eminent physician of a place not far from Harrisburg, I was asked to assist in an operation, a very serious one to perform, in view of its locale over the heart and diaphragm. The field of the operation being near to the solar plexus, there was evident concern expressed as to whether the patient would survive the operation for that very reason. The medical attendants were all prepared, however. The patient after the operation went into collapse. The usual pumping of the legs and arms was resorted to without avail. The etherizer was one of the best in the city. The operation was most thoughtfully and thoroughly performed. Hypodermic injections of restoratives had been made ready prior to the first cut, and were obviously called for, but were not used until subsequent to the following procedure, which is, of course, unpleasant, and, therefore, when it was successful, to avoid a too frequent repetition of it, said restorative injections were given. What was the procedure, gentlemen? When the temporal pulse was not felt and when the patient ceased to breathe, the anal sphincters were slowly, steadily, and persistently digitally dilated. The pulse and breathing most marvelously responded and the patient was saved, and is now, I believe, well. This surgical procedure, now gradually creeping into use, affords, it seems to me, one of the happiest instances of the power of the sympathetic in vital phenomena, and is a procedure, I am constrained to believe, that should be adopted in all cases of suspended animation, whether from surgical or electrical shock, drowning or gas asphyxiation, for it is rapid in action, sure in results, profoundly effective on heart and lung and brain, and may work more quickly than the procedure of depressing the chin and alternately relaxing and drawing out the tongue.

The history of a case in the service of another experienced practitioner was submitted to me for my opinion some two years ago. The prominent symptoms were those embraced in a young lady of twenty-seven

years of age and were of some years' standing, and as follows:

A lump in the throat, as she described it, pain in the epigastric region, a bunch visible at times in the left iliac region, but wandering, and anal pruritus. The grandmother had a tapeworm, the mother ditto, and it was supposed by nine other medical observers of the case that the granddaughter might have it, but yet no lengths of worm had been passed by her. There came to me at once a question of inheritance. Did the granddaughter inherit the tapeworm? Do not smile too readily, gentlemen, for such a question involves prenatal influence, and this factor either had to be present or excluded, and, as is well known, prenatal influence is a marked factor in disease, either by environment or heredity. A tentative diagnosis of nymphomania had been suggested. The grandmother's tapeworm had been passed. The mother's tapeworm! Did it pass before she conceived the patient, her daughter? It did. Hence a prenatal factor was eliminated. Was there any nymphomania? The patient's nails were not trimmed nor were the finger pulps unduly developed or soft. Therefore, nymphomania was excluded. Nothing remained but a physical examination to clear up the diagnosis. From the appearance of the patient's face I was inclined to more readily examine the rectum than the vagina. A rectal digital examination revealed a prolapsed, enormously enlarged left ovary of almost stony hardness. Touching this gave the lump in the throat a sensation of hunger. Firmer pressure gave epigastric pain as well. Why? Because there was a softened condition of the rectal mucosa near the sigmoid, due to ovarian pressure, which conveyed the sensation of sympathetic nerve irritation to the stomach, and resulted in its excess, by reason of a loaded rectum, in epigastric pain. Now, the superficial symptomata of this case might be ascribed to hysteria, pure and simple, for they were confined to sensations of hunger in the throat and stomach and pain in the latter, and we had the bunch as well in the groin, but, of paramount importance in diagnosing the case, all the symptoms disappeared like magic on the taking of food at any and all times of the day and night.

Therefore the superficial symptomata relative to the probable existence of a tapeworm were not very wrongly measured in diagnosis, because I believe sympathetic nerve disturbances are not enough commented upon with sufficient diagnostic acumen in the text-books of the day. Nor could, in this case, the sensations of hunger be correctly estimated in view of the physiological dictum obtaining, that hunger sensation is resident either in the general system, the stomach, or pharynx, for I believe it can evolve anywhere in the intestinal tract, from the tongue to the rectum, causative conditions being anywhere therein present. In this case it could be, and most probably was, caused very often in this rectum when enlarged with fæces, consequently exerting an almost direct action on the gastric branch of the sympathetic, thereby causing hunger sensation and, what is of obvious importance, raising the enlarged ovary into prominence in the left iliac region. With reference to this latter point it must be remembered that the movements of a tapeworm are sometimes powerful enough to raise, in a patient of spare habit like the

one in question, an abdominal bunch anywhere in the abdominal tract, and that it is not only unjust to the movement power of the tapeworm, but even to the patient himself, in the danger that may arise in diagnosis, to attribute such abdominal bunches and movements to the hysterical fancy of the patient, when hysteria in its protean aspect is not at all present.
